ANATOMY.

BOOK II.

DESCRIPTIVE, PARTICULAR, OR SPECIAL ANATOMY.

Special Anatomy.

Special Anatomy may be defined to be that science, the province of which is to determine the situation, shape, and component parts of the several textures and organs of which the human body consists. In the course of this, however, it is requisite to premise some observations on the external shape of the body, and the different regions into which it has, for the sake of greater precision, been divided.

The external shape of the human body is so well known, that it is superfluous to describe it. Besides its division into right and left halves, anterior and posterior surfaces, it is divided into head, trunk, and extremities. The trunk is subdivided into neck (*collum*), chest (*thorax, pectus*), and belly (*abdomen*). The extremities are subdivided into *thoracic* or upper, and *pelvic, abdominal*, or lower.

The shape of the head is ellipsoidal, or oblong spheroidal; the greater diameter being antero-posterior, and the transverse smallest. The neck is cylindrical, spreading out above and below. The shape of the trunk is that of an irregular cylinder, flattened before and behind, broad above, and tapering below the chest, but expanding again at the pelvis. The extremities affect the cylindrical form, inclining to the conical.

Distinction into regions.

These several parts may be still further subdivided. The head is distinguished into two great divisions, the head proper, and the face. The former corresponds to the scalp, and may be divided into coronal, temporal, parietal, and occipital regions. The coronal or syncipital may be reckoned from the anterior margin of the scalp to the site of the anterior fontanelle, or the line named the coronal suture. Behind this to the crown (*vertex*), and downwards on each side, are the parietal or lateral regions; from the parietal and frontal is the temporal; from the crown to the flexure of the neck is the hind-head or occipital (*occiput*); from the last point to the level of the shoulders is the *cervix*; on each side are the lateral regions of the neck; and before is the laryngeal, jugular, or anterior region of the neck (*jugulum*). The face consists of the brow, front or forehead (*frons*), with the *glabella* or *mesophryon* at its base, in the middle, and the eyebrows (*supercilia*) on each side; the nose (*nasus*), the upper lip (*supralabium*), the lower lip (*infralabium*), the chin (*mentum*), the cheeks (*genæ*), the chops (*buccæ*), the upper jaw (*mala*), and lower jaw (*maxilla*).

Besides these, it is usual to distinguish the *prolabium*, or the red portion of the lip, upper and lower, as covered by a thin half-cutaneous, half-mucous skin and epidermis.

Special Anatomy.

The chest, besides its distinction into right and left halves, anterior and posterior surfaces, and upper and lower boundaries, may be distinguished into a sternal region in the middle (*sternum*), a mammary region on each side, an axillary region, a costal region, a hypochondriac region, a scapular region, and a vertebral region.

Several of these regions it is convenient to subdivide in the following manner. The upper anterior region, immediately below the collar-bone, is distinguished as the subclavicular region; the space between the breast and the *axilla* as the extra-mammary region; that between the breast and the sternum as the intra-mammary region; the space below the breasts on each side as the infra-mammary region; the space below the armpit as the sub-axillary region. On the posterior surface of the chest, the space above the spine of the scapula is called the supra-spinal region; that below it the infra-spinal region.

The abdomen may be distinguished into regions in the following manner. The triangular space between the false ribs and navel, commonly named the pit of the stomach, is the epigastric region (*scrobiculus cordis, epigastrium*). Below this, in the centre, is the umbilical (*umbilicus*), with the iliac region or flanks, (*ilia*) on each side, and the hypogastric (*hypogastrium*) below. Behind, on each side of the vertebral column, are the loins, (*lumbi*).

Next to the abdomen is the pelvis, the posterior lateral parts of which are the buttocks (*nates*), the anterior, the *pubes*, and the inferior, the hips or ischiatic regions (*ischia*), with the *perinæum* in the middle between them.

In the trunk of the body, besides the chest, the abdomen, and the pelvis, it is proper to distinguish the region of the back-bone or spine, extending along the whole length of the trunk from the head to the lower end of the trunk. The spine or spinal region is divided into four subordinate regions; the cervical, the dorsal, the lumbar, and the sacral or sacro-coccygeal.

In each pectoral extremity are recognized the following division; the shoulder (*humerus*), the armpit (*axilla*), the arm (*brachium*), the elbow (*cubitus*), the fore-arm (*antebrachium*), the wrist (*carpus*), and the hand (*manus*). The latter is subdivided into the fore-wrist (*metacarpus*), the fingers (*digiti*), the palm (*vola*), and the back-hand (*thenar*).

Each abdominal extremity presents the following separate regions; the haunch (*coxa*), the thigh (*femur*), the knee (*genu*), the ham (*poples*), the leg (*tibia*), of which there is the muscular part or calf (*sura*), the ankle external and in-

Special Anatomy.

ternal (*malleolus externus et internus*), the foot (*pes*), subdivided into the ankle-joint (*tarsus*), the foot-joint (*metatarsus*), the toes (*digiti pedis*), with dorsal or upper surface, and plantar surface or sole (*solea*).

These divisions, though not so numerous as they have been made by some, are sufficiently so for the purpose of general anatomical description. Where more minute distinction is requisite, it shall be introduced as we proceed.

Descriptive or Special Anatomy includes not only the descriptions of the situations and relations of the different classes of textures in the human body and that of the internal organs, but it comprehends also a particular form of anatomical knowledge necessary to the surgeon. This consists in defining, as accurately as language and measurement can do, the boundaries of the different regions into which the human body may be divided, and ascertaining the positions and relations of all the important parts that are liable to become the seat of local disease and chirurgical operation. To this department the names of Chirurgical Anatomy, Topographical Anatomy, and Anatomy of Regions, are given.

The limits within which the present article must be confined permit not to enter upon this department of Anatomical knowledge. It is sufficient to say, that useful treatises on this subject have been published by Velpeau, Blandin, Edwards; and that in the systems of operative Surgery, especially that by Mr William Fergusson, and the work of Mr Maclise, correct information upon the boundaries and the relative positions of the various regions is communicated.

Stature.

The stature of the body varies in the two sexes, in individuals, in families, in tribes, and in nations. The Romans, when they first visited Gaul, remarked the gigantic stature of the ancient inhabitants of that country compared with themselves; and, generally speaking, the modern Italians, though by no means a pure or unmixed breed from the ancient stock, are a diminutive race. The Germans, and most of the English and Irish, are rather tall. The inhabitants of Finland are distinguished for their great stature, amidst the dwarfish tribes by which they are surrounded. In general the Europeans are taller than the Asiatics.

Height or length.

The average height of the adult male varies from 5 feet 8 inches to 5 feet 10 or 11 inches, or even to 6 feet. The dimensions of different parts vary according to those of the whole body; but the following measurements of a male of 5 feet 8 inches, and one of 5 feet 11 inches, may communicate some idea of the length of different regions of the body.

	Inches.	Inches.
Total height	68·00	71·00
Between the tips of the middle fingers, with the arms extended	68·00	72·75
From the crown to the pubes	34·00	45·00
From the crown to the lower tip of the chin	9·75	9·00
From the tip of the chin to the top of the breast	3·85	3·25
From the top of the breast to the pit of the stomach	6·08	9·75
Between the pit of the stomach and the navel	6·08	7·00
Between the navel and top of the pubes	6·08	6·75
Between the top of the shoulder and the bend of the elbow	12·06	12·00
From the bend of the elbow to the top of the hand	10·02	10·5
The hand, from the wrist to tip of middle finger	7·75	7·375
Between the top of the thigh inside and the knee inside	14·06	17·00
From the knee inside to the sole	18·05	20·00
The foot, from the heel to the point of the great toe	9·75	10·00

The average height of the female varies from 5 feet 3 inches to 5 feet 5 inches and 5 feet 7 or 8 inches. A woman of 5 feet 10 inches is unusually tall. The length of the different regions is proportionally less than in the male.

The length of the body previous to adult age varies with the period of life. The length of an embryo of three weeks, represented by Soemmerring, is about $\frac{1}{8}$ of an inch; one of eight weeks is about 1 inch; and one at the end of the fifth month is about 10 inches. According to Burns, however, the length of the fœtus in the fifth month does not exceed 6 or 7 inches; in the sixth it is about 8 or 9, in the seventh about 12, and in the eighth about 15 inches. At the period of birth, the average length, according to Roederer, is about $20\frac{1}{2}$ inches.

The only part of the fœtus of which it is important to determine the average dimensions at the period of birth is the head. Its largest diameter, which is that from the crown to the chin, is in general about 5 inches. The transverse diameter between the parietal protuberances is at the same time about $3\frac{1}{2}$ inches. Of 60 male and 60 female infants born at the full time, whose heads were measured by Dr Clarke, the circumference passing through the occipital process and the middle of the brow was at an average 13·8 inches, while the arch from ear to ear over the crown was 7·32 inches. One measured 15 inches in circumference, and one $8\frac{1}{2}$ inches from ear to ear; but none were under 12 inches in the one direction, or $6\frac{1}{4}$ inches in the other.

It is well established that there is a difference in the average dimensions of the male and female, even in the fœtal state. Roederer found the mean length of 16 male children born at the full time to be $20\frac{8}{12}$ inches, and of 8 females only $20\frac{4}{12}$; and of the 60 male and 60 female infants measured by Dr Clarke, the average circumference was 14 inches in the former, and only $13\frac{5}{8}$ in the latter; and the parietal arch was $7\frac{1}{2}$ in the former, and $7\frac{1}{5}$ in the latter. Of 120 infants, in 6 only, which were males, did the circumference of the head exceed $14\frac{1}{2}$ inches.

Weight.

The weight of the adult male varies from 9 stone to 11 or 12. Ten stones, or 140 lb., may be stated as the average. The female weighs about 8 stone, and rarely more than 10. After the age of 35 or 40, when fat begins to be deposited, the weight rises considerably; and the average weight at this age is from 13 to 14 stones. In some extraordinary examples of corpulence, combined with large stature, the weight of the body amounts to 20 and 25 stones.

The average weight of the fœtus in the early months is uncertain. According to Mr Burns, it weighs about 2 oz. in the 12th week; about 1 lb. in the 6th month; and about 4 or 5 lb. troy in the 8th month. At the period of birth the mean weight is about 7 lb. avoirdupois. Dr William Hunter states, that of several thousand new-born perfect infants weighed at the British Hospital in London by Dr Macaulay, the smallest was about 4 lb., the largest about 11 lb. 2 oz., and the greater number varied from 5 to 8 lb. avoirdupois. He knew no instance of a new-born infant weighing 12 lb. Of 60 male and 60 female infants weighed by Dr Clarke, the lightest was 4 lb., the heaviest 10 lb., and the average 7 lb. 13 dr. avoirdupois. The average weight of 26 children at the natural period, weighed by Roederer, was about $6\frac{1}{2}$ lb.; the lightest about $5\frac{1}{2}$ lb. and the heaviest about 8 lb.

The difference between the weight of the male and female infant at birth is estimated by Dr Clarke at about 9 oz. avoirdupois, which agrees with the results obtained by Roederer.

In the case of *twins*, the average weight of each twin is in general less than that of children born at single births; but the combined weight of both is greater. Dr Clarke found the average weight of 12 twins to be 11 lb. avoirdupois each pair; the heaviest being 13 lb., and the lightest $8\frac{1}{4}$ lb. Mr Burns, however, states that he has known instances in which

Special Anatomy.

each twin was rather above than below the usual weight of a single-birth child.

Average weights of Individual Organs.

An important and useful point is to determine the average size and the dimensions of the principal organs of the human body in the adult state. Krause has, with this view, given the measurements of all the regions and the dimensions of most of the organs. All these modes of estimating the size of organs, however, are fallacious. The only one which can be employed with any precision is to ascertain the average weights of organs, and to note the proportion which these weights bear to that of the whole body. Attempts of this kind, applying, however, only to certain organs, have been made by different inquirers.

The organs specified were found, according to numerous trials made by Dr Clendinning, in males between the ages of 21 and 60 years, to weigh on an average, at the following rates:—

	Oz.		Gr.		Lb.	Oz.
Brain................	$46\frac{1}{4}$	=	20,226	=	2	$14\frac{1}{4}$
Heart................	$9\frac{1}{16}$	=	3,982			
Liver................	$53\frac{1}{2}$	=	23,408	=	3	5
Kidneys.............	$9\frac{1}{5}$	=	4,025			
Spleen	5	=	2,188			
Pancreas	$2\frac{5}{8}$	=	1,148			
Stomach	5	=	2,188			
Lungs	46	=	20,116	=	2	14

In the same persons the whole person weighed $94\frac{1}{2}$ pounds, which is between 46 and 48 pounds less than the average, 140 or 142 pounds (Quetelet), at the age of 40 years.

Among the persons weighed, however, several were 124, 125, and 126 lb.; two weighed 140 lb., one weighed 133 lb., and one at 50 years weighed 200 lb.

These results differ in a very slight degree from those obtained by Dr Reid and Dr Peacock in the Royal Infirmary, Edinburgh. In 89 males the average weight of the heart amounted to 11 oz. 1 dr.; in 53 females to 9 oz. $\frac{1}{4}$ dr. In 60 males the average weight of the liver was 52 oz. $12\frac{1}{2}$ dr.; in 25 females 45 oz. $3\frac{1}{4}$ dr. The right kidney weighed, on an average in the male 5 oz. 7 dr.; in the female 14 oz. 13 dr. The left kidney 5 oz. 11 dr. in the male; in the female 5 oz. 2 dr.

The average weight of the whole brain (*Enkephalon*) in 131 males, between the ages of 25 and 55 years, was found to be 50 oz. $3\frac{54}{131}$ dr.; in 74 females between the same periods to be 44 oz. $14\frac{28}{74}$ dr.; giving a difference of 5 oz. 4·95 dr. in favour of the male brain.

The average weight of the brain proper (*Cerebrum*) in 95 males between the ages of 25 and 55 years, was found to be 44 oz. 3·4 dr.; in 58 females within the same periods to be 39 oz. 3·3 dr.; making a difference of 5 oz. 0·1 dr. in favour of the *cerebrum* of the male.

Special Anatomy has been divided, according to the classes of textures of which the human body is composed, into different parts, with appropriate denominations. Thus the anatomy of the bones has been named *Osteology*, *Osteography*, and *Skeletology*; while that of the soft parts in general has been denominated *Sarkology*. Where more minuteness is attempted, the anatomy of the soft parts has been still further subdivided into that of the ligaments, *Syndesmology*; the muscles, *Myology*; the vessels, *Angiology*; the nerves, *Neurography* and *Neurology*; the membranes, *Hymenology*; the glands, *Adenography* and *Adenology*; and the internal organs, *Splanchnology*.

Though these are convenient terms to designate the several divisions of Special Anatomy, they afford little assistance in the general arrangement of the subject. It is justly observed by Bichat, that this arrangement, if such it can be named, is objectionable, by separating different organs which ought to be united. It is indeed remarkable only for connecting organs by arbitrary, and often unnatural principles; and though it may answer in a subordinate manner, it is unfit to furnish the principles of a general and natural mode of arrangement.

Special Anatomy.

The most eligible method is that which arranges the organs according to their physiological purposes,—a method adopted by Haller and Soemmering, but which required the hand of Bichat to give it its full and perfect developement, and which has since been adopted from this author by most subsequent writers.

According to this method, the organs of the human body may be arranged in three great classes: *first*, those pertaining to the animal functions, or which establish the connection between the individual and the objects of the external world—the organs of *relation*; *secondly*, those pertaining to the organic functions, or which tend to the continuance of the individual—the organs of *nutrition*; and, *thirdly*, the organs relating to the continuance of the species—the organs of *reproduction*. The first class contains the organs of locomotion, speech, and sensation; the second those of digestion, circulation and absorption, respiration, and secretion; and to the third are referred the organs of generation.

This method may not be altogether free from objections; several of which are anticipated by Bichat. It is sufficient, however, to observe that it is less objectionable than any other; and one of its advantages is, that it furnishes a clearer and more precise idea of the connection of the different classes of organs of the animal body than any other yet proposed.

This method of arrangement may be conveniently exhibited in the following table.

I. *Organs pertaining to the Animal, Voluntary, or Relative Functions.*

1. Locomotion.	Instruments—Bones, Cartilages, Ligaments, and Fibro-cartilages. Agents—Muscles, Tendons, and their appendages.
2. Sensation.	The Organs of Proper Sensation—Smell, Sight, Hearing, and Taste. The Organs of Common Sensation—Touch, Tact, &c.
3. Voice.	Laryngeal Voice—the Larynx. Oral Voice or Speech—the Lips, Tongue, and Teeth.
4. Nervous Energy, or Innervation.	Central Organs—Brain, Cerebellum, and Spinal Chord. Distributed Organs—the Nerves.

II. *Organs pertaining to the Organic or Nutritive Functions.*

1. Alimentary or Limitrophic Function.	Digestion.	Mastication—Mouth, Tongue, and Teeth. Deglutition—Pharynx and Œsophagus. Chymification—Stomach. Chylification—Duodenum and Ileum. Defecation and Excretion—Colon and Rectum.
	Lacteal Absorption—Lacteals and Thoracic Duct.	
2. Circulation.	Nutritive Circulation—Heart and Blood-vessels. Aerating Circulation, or Respiration—Lungs, &c. Secretory Circulation, or Secretion—Glands.	

III. *Organs pertaining to the Reproductive Function.*

Generation.	Male or Impregnating Organs. Female or Ootrophic Organs.	Product—the Fœtus.

Special Anatomy.

PART I.

ANATOMY OF THE ORGANS OF THE ANIMAL, VOLUNTARY, OR RELATIVE FUNCTIONS.

The organs belonging to the functions of animal life are those of locomotion, sensation, voice, and innervation. These organs are distinguished by two general characters, symmetry of form and harmony of action. By the first is meant that each organ possesses similar parts on each side of the mesial plane. By the second is meant that the action of that part which is on the right side of the mesial plane corresponds with that on the left.

CHAP. I.—THE ORGANS OF LOCOMOTION.

The organs of locomotion may be arranged in two orders, active and passive. The first are the agents of motion, or the organic substances which produce motion; the second are the bodies moved, or the instruments of motion. The muscles, strictly speaking, are the former, though to these are added certain appendages. The bones and their appendages constitute the second.

With the latter order of parts it is usual to begin the business of special anatomy, for obvious reasons. The bones are at once the most durable and regular in shape of all the organic solids; and as an intimate relation subsists between their mechanical figure and the soft parts connected with them, the knowledge of the former constitutes the best introduction to that of the latter species of organs.

SECT. I.—OSTEOLOGY, SKELETOLOGY.

The assemblage of bones composing the human body constitutes the skeleton, which, like the body, is divided into head, trunk, and extremities. The length of the skeleton is about an inch less than that of the body; that is, the skeleton of an individual 5 feet 8 inches in height is about 5 feet 7 inches long, and of one 6 feet, about 5 feet 11 inches long. The weight of the skeleton varies at different periods of life. That of a middle-sized adult ranges between 160 and 200 ounces. A male skeleton, measuring 5 feet 6 inches long, I found to weigh 168 ounces, or $10\frac{1}{2}$ lbs., avoirdupois.

The number of separate pieces amounts to 254, of which 56 belong to the trunk, 60 to the head, 72 to the pectoral extremities, and 66 to the pelvic. Of these several parts, the trunk is the most important, because, 1*st*, it is developed before the head or extremities; and, 2*dly*, because if we look to its place in the animal kingdom generally, it is the most essential and constant, and presents the general *modulus* or type according to which the osseous pieces composing the head are constructed.

The Trunk.

The trunk. The trunk of the skeleton consists of three parts, the spine or vertebral column, the chest or thorax, and the pelvis.

§. 1. *The Spinal or Vertebral Column.* (*Spina Dorsi; Vertebræ.*)

The vertebral column. The vertebral column, situate in the posterior part of the trunk, the length of which it determines, unites the head to the pelvis, supports the former, and is supported by the latter. When completely developed, it consists of 29, and rarely of 30 pieces, named *vertebræ* (*spondyli*, *σπονδυλοι*), from the circumstance that each admits of a slight degree of rotatory motion. Twenty-four of these bones, which are in the healthy adult separate, are denominated true vertebræ (*vertebræ veræ*). The 25th, named the *sacrum*, though in adult life forming a single bone, consists in early life of four separate pieces, which become consolidated, and are therefore named false *vertebræ*, (*vertebræ spuriæ*). The four last constitute what is named the *coccyx*. The column thus formed, though straight at birth, assumes afterwards several curvatures in the antero-posterior direction, giving it the aspect of the Italian *ʃ*. It may be divided into four regions, the cervical, dorsal, lumbar, and sacral. In the first it is almost straight, but begins to bend backward in the second, so as to form a considerable curvature with the convex surface posteriorly. A little below the middle of the dorsal portion it bends forward, and continues to do so to the lower part of the lumbar region, where it once more bends backward, and forms the sacrum into a concave hollow. At the lower end of the sacrum it again inclines forward, and the coccyx is in general considerably incurvated anteriorly. (Plate XXVI. fig. 1.)

Special Anatomy.

The vertebræ.

Besides the antero-posterior curvatures, there is in general a lateral one near the lower part of the dorsal region, on the left side, to which its concavity is directed. This has been observed by anatomists, from Cheselden, who first represented it, to Soemmering, Bichat, and Meckel.

In length the vertebral column does not vary much; and differences in stature depend more on the dimensions of the members than of it. In thickness it augments progressively from the cervical to the sacral portions, after which it once more tapers to a point. It may be compared to two cones united by their base, the superior of which is truncated.

The vertebræ, true and false, possess certain common characters. Of these the most general is the annular shape, or a ring of bone, the opening of which, in continuity with those of the whole column, constitutes a longitudinal cylindrical cavity for lodging the spinal chord and its envelopes. It is therefore denominated the hole of the spinal marrow (*foramen medullæ spinalis*, Soem.), or simply the vertebral hole (Bichat). Anterior to this is a mass of bone, generally the largest of the vertebra, and therefore named its body (*corpus vertebræ*). The anterior surface is flat, sometimes slightly convex; the posterior is always concave; the upper and lower surfaces are slightly concave, and correspond with the intervertebral fibro-cartilages.

Behind the hole the vertebra is moulded into an arch or annular segment, the outer surface of which forms seven processes. The first at the back of the vertebra on the median line is the *spinous process*, which may be said to be formed by the union of the spinal plates in the middle. On each side are two, which, from their situation with respect to the column, are named *transverse* processes. Other four, two on the upper and two on the lower surface of each vertebra, near the base of each transverse process, are named *oblique*, from their direction, and *articular* (*processus articulares*), because the inferior ones of the superior vertebra are articulated with the superior ones of the lower vertebra. These processes are easily distinguished by being covered with cartilage and synovial membrane. They constitute true capsular joints.

Each vertebra presents four notches or depressions, two at the upper and two at the lower surface, between the body and the oblique processes. Each of these, with corresponding notches on the vertebra above and below, forms a hole (*foramen conjunctionis, vel intervertebrale*), for the exit of the spinal nerves and the entrance of blood-vessels.

Special Anatomy.

The vertebræ.

All the vertebræ, excepting the *atlas* and *vertebra dentata*, are united in the same manner, and at the same points. The bodies are united by the intervertebral fibro-cartilages, which consist of white concentric annular layers of fibrous matter, placed in juxtaposition, and containing internally semifluid jelly. In adults this substance becomes firm and consolidated; but in the young subject it is so soft and compressible, that young persons are found to be one or two inches taller in the morning, or after they have been some time in the recumbent position, than in the evening, or after the spinal column has sustained for some hours the weight of the person. In advanced life these fibro-cartilages become still more solid and shrivelled; and in some instances they are converted into bone, so as to unite two or more vertebræ in a single mass. This change is one reason of the greater stiffness and incurvation of the spine in the old and decrepid, than in those in early life.

Besides the connection by the intervertebral cartilages, the vertebræ are united at their articular processes by means of capsular ligaments, so as to allow slight flexion and extension on each other; and at the basis of the spinous processes, by means of short, firm, and inelastic yellow chords (*ligamenta flava*), named yellow ligaments. These, with a thick fibrous fascia extending along the anterior surface of the bodies (*ligamentum anterius, fascia longitudinalis anterior*), a similar fibrous fascia behind, lining the vertebral canal, a ligament connecting mutually the apices of the spinous processes, and the incumbent muscles, retain the vertebræ firmly in their places, and prevent them from being dislodged, unless by a force adequate to break the bones and rend the ligaments.

The vertebræ vary in structure. The bodies consist chiefly of loose cancellated tissue, without solid bone. The spinal rings and the processes are much more firm and dense.

In the fœtus and infant each vertebra consists of three portions, a thick, loose mass, corresponding to the body, and two lateral arches corresponding to the spinal rings, without spinous process, and scarcely meeting. In the fœtus, indeed, the posterior wall of the vertebral canal may be said to be incomplete. Soon after birth, however, the spinal plates enlarging, mutually coalesce on the median line; and from this point of union, by successive accretion, the spinous processes are gradually formed. These facts may serve in some degree to explain the facility with which tumblers and rope-dancers may be habituated in infancy to the most extraordinary inflexions of the trunk.

The vertebræ, agreeing in the characters now enumerated, differ from each other according to the regions which they occupy, and the parts with which they are connected. On this principle the twenty-four true vertebræ are arranged in three classes; the cervical (*v. cervicis*), the dorsal (*v. dorsi*), and the lumbar (*v. lumborum*).

The cervical vertebræ are in number generally seven, rarely six or eight; the dorsal are twelve; and the lumbar are five. (Plate XXIV. and XXV. fig. 1.)

The cervical vertebræ.

The cervical vertebræ are distinguished by their bodies being small, with flat anterior surfaces; by the articular processes being short and flat, as well as less oblique than those of the others; by their transverse processes being short, of a triangular shape, hollowed above, and perforated at the base by a hole for the transit of the vertebral artery; by the spinous processes being short, nearly horizontal, and generally bifid; and by the vertebral hole being large and of an oval shape.

The atlas.

The first and second of these vertebræ are still further distinguished by peculiarities of configuration. The first, which is named *atlas*, consists of a large bony ring, inclosing an irregular hole, approaching to the shape of the ancient lyre. Instead of the body, which is wanting, is a mere arch of dense bone, with an obtuse tubercle before for the *longus colli* muscle, and behind an articular facette which applies to a corresponding one of the tooth-like process of the second vertebra. From the extremities of this arch the vertebral hoop acquires considerable thickness, for the formation of the oblique and transverse processes. The superior oblique process is seen above on each side in the form of an elliptical cartilaginous surface, slightly concave, consisting of two parts, the anterior large, the posterior small, and terminating in a point which overhangs the sinuosity of the vertebral artery. The cavity of this superior oblique process receives the condyloid process of the occipital bone, with which it is connected by a capsular ligament, lined by synovial membrane. Below is seen the articular facette of the inferior oblique process, rounder, shorter, less concave, but covered also by cartilage and synovial membrane, and articulated with the superior processes of the second vertebra. Between these two, on the lateral regions of the vertebral ring, is the transverse process, in the shape of a triangle, the base of which is formed by the bone of the oblique processes, and the sides by the production of the anterior and posterior arch. The latter, being the segment of a smaller circle, is more distinctly circular than the former, and may be described as a strong, dense, semiannular piece of bone, with a tubercle on its posterior margin at the median line, to which the *rectus capitis posticus minor* is attached. On the inside of the atlas, at the lower margin of the superior oblique process, is a rough surface with a depressed cavity, which marks the insertion of the transverse ligament. The space anterior to this is occupied by the tooth-like process of the second vertebra; that posterior to it, which is the proper vertebral hole, by the beginning of the spinal chord.

The atlas is connected above to the occipital bone by the capsular ligament, which surrounds the margins of the superior oblique processes; below, to the *vertebra dentata* in the same manner; and behind its anterior arch to the tooth-like process. To its anterior tubercle are attached the *longus colli* and *rectus capitis internus minor*; to the transverse process the *rectus lateralis*, the superior and inferior oblique muscles, the *levator anguli scapulæ*, the *transversi*, the *scalenus anticus*, and the *transversus colli*. To its posterior arch the *rectus posticus* is attached.

By the condyloid processes of the occipital bone moving on the superior oblique processes, the head is bent and extended, or moved backwards and forwards on the atlas.

The atlas ossifies by two points.

The axis.

The second vertebra, named *axis* and *epistropheus*, from its motions, is distinguished by a large prominent body like a tooth (*processus odontoides*) issuing vertically from its body, a circumstance from which it is also named *vertebra dentata*. This process, which is a four-sided prism, with the top obliquely acuminated, presents on its anterior surface an articular facette, corresponding to that of the atlas. The posterior surface is rough, and corresponds to the transverse ligament. From the odontoid process the body descends somewhat below the level of the vertebral hoop, and presents at its lower margin, on the median line, a tubercle, with excavations on each side. Above, on each side of the odontoid process, are the superior oblique processes, in the shape of oval facettes, covered by cartilage and synovial membrane, and articulated with the inferior oblique processes of the atlas. Below, and a little behind, is the inferior articular process, more oblique in direction, and articulating with that of the third vertebra. Between the two is the transverse pro-

Special Anatomy.

The vertebræ.

cess, with the vertebral hole in its base; and from the same point the spinal plates converge backwards so as to form the spinous process, which is distinct and bifid in this vertebra. Between the superior oblique process is the upper notch, which is rather a rounding of the spinal plates than a distinct depression; and between the inferior oblique process and the transverse process is the lower notch, which, with the upper one of the third vertebra, forms a complete hole for the exit of the fifth pair of spinal nerves.

The vertebral hole in this vertebra is heart-shaped, the basis before and the apex behind.

By the odontoid process it is articulated with the occipital bone and the atlas; by the upper oblique process with the atlas; and by the lower oblique process with the third cervical vertebra.

To the transverse process are attached the *splenius capitis, levator anguli scapulæ, scalenus, transversus cervicis, longus colli, intertransversalis secundus anterior et posterior.* To the spinous process are attached the *rectus capitis posticus major, obliquus inferior, spinalis cervicis, interspinalis cervicis,* and *multifidus spinæ.*

The axis ossifies from four points, one for each side, one for the body, and one for the odontoid process.

The third, fourth, fifth, and sixth cervical vertebræ are very similar. The bodies gradually increase in size to the seventh, which is generally the largest. The articular processes are also more oblique in the lower ones than in those above. The spinous processes also increase in size in the lower cervical vertebræ, and in the sixth and seventh are particularly large and prominent; and in the last are not bifid, but merely tubercular. The vertebral holes in the second and third are heart-shaped, and the lower ones triangular, with the apex towards the spinous processes. The body of the seventh also presents at its lower margin a depression, which, with a corresponding one in the first dorsal, receives the head of the first rib. The seventh, in short, may be regarded as indicating the transition from the cervical to the dorsal vertebræ.

Besides the muscles already mentioned as attached to the *axis,* to the cervical vertebræ are attached the *lumbo-costalis,* the *serratus posticus superior,* the *rhomboideus minor,* the *cucullaris,* the *splenius capitis,* the upper part of the large *complexus,* and part of the *rhomboideus major.*

The dorsal vertebræ.

The dorsal or thoracic vertebræ (*v. dorsi vel thoracis*), which are twelve in number, are distinguished by articular notches on their superior and inferior margins, which, with the intervertebral cartilage and the contiguous vertebræ, form depressions for lodging the heads of the ribs, and cartilaginous facettes on their transverse processes for articulating with similar facettes on the tubercles of the ribs. The tenth dorsal vertebra has often only one facette above, and the eleventh and twelfth have only a single facette for each of the two last ribs.

The bodies of the dorsal vertebræ are more convex and somewhat rounder before than those of the cervical and lumbar. The hole, which is smaller, is also rounder, approaching to the oval shape.

The spinal plates are broad and strong, and meet behind in long prismatic spinous processes, which are directed obliquely downwards, so that they are imbricated over each other, especially in the middle of the back. The three last are less oblique. The oblique direction and imbricated arrangement of the spinous processes are connected with the peculiar flexuous bend which the column undergoes from the lower part of the cervical to the upper end of the lumbar region.

The twelfth dorsal vertebra approaches the first lumbar in the large size of its body, in the shortness of its transverse processes, in the straight direction and smaller extent of the spinous process, and in the articular processes becoming almost vertical.

To the dorsal vertebræ the following muscles are attached: the *splenius capitis et colli, trachelo-mastoideus,* the part of the *complexus* called *biventer cervicis,* the *complexus, longus colli, transversus colli, spinalis colli, semispinalis dorsi, multifidus spinæ,* the inner part of the *lumbo-costalis,* the *levatores costarum,* the inner layer of the tendon of the internal oblique and transverse muscles of the belly, the *latissimus dorsi, rhomboideus major, cucullaris,* and *serratus posticus superior et inferior.*

The lumbar vertebræ.

The five lumbar vertebræ are distinguished by the size of their bodies and their processes, and by the direction of the spinous and articular processes. Each body is both broader and thicker, but less convex, than those of the dorsal vertebræ. The vertebral hole also is larger, and it resumes the triangular shape as in the neck. The transverse processes are broad, flat, and large, without articular facette like the dorsal, or arterial hole like the cervical, and are rough by the attachment of the *sacro-lumbalis.* Of the articular processes, which are large and have a vertical direction, the upper is concave, oval, and turned towards the median plane; the lower is convex, oval, and directed towards the lateral regions. The spinous processes are large, flattened, almost square, with thick obtuse margins, and directed straight backwards. The vertebral notches are large, and form holes much larger than at any other part of the spine.

The attached muscles are the *spinalis dorsi, multifidus spinæ, quadratus lumborum,* the inner layer of the internal oblique and transverse, and the outer layer of the latter, the external and internal parts of the *lumbo-costalis,* the *latissimus dorsi, serratus posticus inferior,* the diaphragm, and the *psoæ.*

The sacrum.

The *sacrum,* composed in early life of five pieces, which are afterwards consolidated into one, may be regarded as a series of imperfect vertebræ conjoined into a single mass. It is a symmetrical bone, of a triangular shape, with the base attached to the last lumbar vertebra, the apex, which is obtuse, adhering to the *os coccygis,* and the sides wedged between the bones of the pelvis.

The anterior or pelvic surface is concave, with the base, sometimes named the *promontory,* prominent and overhanging, the apex and the lateral margins incurvated forwards, and corresponds to the rectum. It presents in general four, sometimes five pairs of oval holes, which communicate with the spinal cavity, and between each of which may be seen a transverse ridge marking the lines of junction of the several bones; and in some instances the inner is so imperfect that a deep line is left. These holes, therefore, through which the nerves pass from the spinal chord, are quite analogous to those formed by the union of the vertebral notches. The posterior surface of the sacrum is much more irregular. At the top are two articular processes, concave and cartilaginous, for receiving the convex surface of the inferior articular processes of the last lumbar vertebra. Outside of these is a deep notch, which, with that of the same vertebra, forms the posterior vertebral hole; and outside of this is a tubercle, which corresponds to the transverse processes of the true vertebræ. Below the notch on each side is a series of four holes, which, like those of the anterior surface, communicate with the cavity of the bone, and allow the posterior nerves to issue from the chord. On the median line, between, there is an irregular bony ridge, or rather a series of three spinous processes, short, obtuse, and separated by shallow depressions. The third of these diminishes gradually in the longitudinal direction till it is entirely lost

Special Anatomy.

The vertebræ.

opposite the fourth pair of sacral holes, leaving between two ridges a triangular opening, which often communicates with the interior of the spinal cavity, and, when it does not, marks the lower termination of that cavity. In the former case it is closed by the posterior sacro-coccygeal ligament.

The sides of the sacrum, which are rough, and of an irregular cuneiform shape, present two surfaces,—one anterior, something cartilaginous, for articulating with the iliac bones,—the other posterior, marked by two deep sinuosities, in which are lodged the sacro-iliac ligaments. The inferior termination of the sides tapers towards the apex or coccygeal end. The surface is rough for the insertion of the sacro-ischiadic ligament, and it is terminated by a notch for the exit of the fifth pair of posterior sacral nerves.

The structure of the sacrum, like that of the vertebræ, is cancellated, and most loose in the site of the spinal plates and processes. Its mode of ossification is analogous to that of the vertebræ generally. On the middle plane appear five points, which correspond to the bodies of the false vertebræ, or the individual bodies of the sacrum; and on each side of these are formed two others, which become eventually the ridges of bone between the anterior and posterior sacral holes and the spinal plates. As these enlarge, they coalesce; and consolidating, leave only on the pelvic and dorsal surfaces the rows of holes through which issue the sacral nerves. It hence results that the sacrum is ossified from fifteen separate portions of bone.

Besides the muscles connected with the lumbar vertebræ, the sacrum gives attachment to part of the *glutæus maximus* and the *pyriformis*.

The *sacrum* is attached above to the last lumbar vertebra by the intervertebral fibro-cartilage, the capsule of the two articular processes, and the yellow ligament of the spinous processes; to the iliac bones by the sacro-iliac *synchondrosis*, and to the coccyx by a similar fibro-cartilage. (Plate XXIV. fig. 1, S.)

The os coccygis.

The *coccyx* is a symmetrical bone, triangular, occupying the posterior and inferior parts of the pelvis, attached by its base to the sacrum, and with the apex free and slightly incurvated forwards, so as to terminate in a hooked point, which has been supposed to resemble the bill of the cuckoo, (*κοκκυξ, cuculus.*)

The anterior or pelvic surface is concave, marked with transverse grooves covered by periosteum, and supporting the lower extremity of the rectum. The posterior or outer surface is convex, gibbous, and unequal, for the insertion of the sacro-coccygeal ligament and some fibres of the large *glutæus*, and, like the anterior, is also marked by transverse grooves.

The base or upper end of the coccyx is concave before for articulation with the sacrum, and presents behind two tubercles continuous with those of the spinal region, and on the sides two notches, which, with those of the sacrum, form holes for the fifth pair of sacral nerves. The margins of the bone are rough, for the attachment of the small sciatic ligament, and meet below at an angle, which is sometimes bifid, sometimes obtuse, and to which the *levator ani* is attached.

The coccyx is generally cellular, with little density. The transverse grooves by which it is marked indicate its original separation into five portions, two of which becoming united, leave four and occasionally three portions, an upper, a middle, and a lower. These portions, indeed, are so long in consolidating, that they are often separate in the adult. The first is the largest, and resembles a diminutive vertebra without hole, and with truncated or undeveloped processes. A lateral portion on each side projects like a wing, the rudiments of the transverse processes; and the two tubercles above noticed, rising like horns, are imperfect articular processes, meeting those of the *os sacrum*. The bony ridge which descends from these are imperfect spinal plates; and as these do not meet, they leave between them a groove corresponding to the anterior half of the vertebral hole; and the spinous processes are wanting. In the second coccygeal bone, which is rounder than the first, the aliform portions corresponding to the transverse processes are also smaller than in the first; and in the third and fourth they are diminished so much that they are scarcely cognizable.

Special Anatomy.

The spine.

The spine generally.

The series of bones now described form by their union what is called the backbone, chine, spine (*spina dorsi*), or vertebral column. Viewed in connection, it may be distinguished into an anterior and a posterior region, two lateral surfaces, a base, and an apex.

The anterior region is large in the neck, narrow in the back, and broad in the loins and pelvis. A series of transverse grooves of variable depth marks the bodies of the vertebræ; and a series of transverse elevated ridges distinguishes in like manner their upper and lower margins. These grooves, which in the cervical vertebræ are confined to the front, extend in the dorsal and lumbar to the sides. This anterior region is covered by the anterior vertebral ligament. On the sides it answers in the neck to the anterior or great *recti*, and the *longi colli* muscles; in the chest to the latter, to the *vena azygos* on the right, and the thoracic aorta on the left; in the abdomen to the abdominal aorta and the inferior cava; and in the pelvis to the rectum.

In the posterior region are seen, on the mesial plane, the row of spinous processes, horizontal above and below, and imbricated in the middle. The intervals, which are considerable in the neck and loins, are much contracted in the back, in which extension brings the processes in contact. The apices of all are in general in the same straight line; but this may be disturbed, either from the wrong direction of a process, or an unnatural position of a vertebra.

On each side are seen the intervertebral grooves (*fissuræ interspinales*), which commence at the occipital bone, and are continued with those of the sacrum. Broad and horizontal above, smaller and more oblique in the middle, very narrow below, these grooves are formed by the series of spinal plates, between which are left spaces varying in size according to the obliquity of the plates. These spaces are occupied within by the yellow ligaments, which being inserted at their inner surface, are something broader than the spaces, and without by the *transversus spinæ* muscle.

On each side also is recognised a longitudinal hollow, extending from the atlas to the lower end of the sacrum. This hollow, which is formed by the spinous processes and the transverse processes with the spinal plates below, is superficial at the neck, narrow and deep in the back, and narrow and superficial at the loins and sacrum. In this longitudinal groove is lodged the muscle named *multifidus spinæ*. (Plate XXV. fig. 1.)

The lateral regions present first the row of transverse processes, which vary in direction in different regions, chiefly in consequence of the spinal curvatures. Thus, if a vertical plane pass down along the sides of the column, the transverse processes of the neck and loins will be anterior to it, while those of the back will be behind it. In the first region these processes are distinguished for forming, by the series of holes in the base of each, a bony canal traversed by the vertebral artery, and which is com-

pleted in the intertransverse spaces by the *intertransversales colli.* To these transverse processes numerous muscles are attached. Between them in the neck, and anterior to them in the back and loins, is a series of holes formed by the union of the vertebral notches. Through these, which are the intervertebral holes (*foramina intervertebralia*), and which increase in size from the neck to the loins, where they are considerable, the anterior branches of the spinal nerves pass. Their shape is elliptical and their transit short. Anterior to these processes in the dorsal vertebræ are the depressed facettes, in which, with those of the fibro-cartilages, the heads of the ribs are lodged.

The base of this column, which is supposed to be the last lumbar vertebra, is articulated with the sacrum in such a manner as to form an anterior convexity and a cavity behind. The base, however, may with greater justice be placed in the upper half of the sacrum, which, being firmly wedged between the thick posterior margins of the iliac bones, transmits to them, and thereby to the bones of the pelvic extremities, the weight of the trunk. The mechanism of this is similar to that of the keystone of an arch, which the sacrum truly represents. The perpendicular pressure on this bone is counteracted and balanced by the lateral pressure of the iliac bones; and this lateral pressure is sustained, partly by their mutual pressure on each other before at the pubis, but chiefly by the oblique pressure of the neck of the thigh-bone, and the perpendicular pressure of the cylinder of the latter and those of the leg-bones.

The upper extremity of the column, which is formed by the atlas and axis, receives the weight of the scull and its contents, which are exactly balanced on the articular cavities of the former bone. On this also the head is bent or extended by its proper muscles. Rotation is performed by the motion of the atlas with the head on the articular cavities of the second vertebra, and round its odontoid process.

The holes of each vertebra form, by union, the vertebral canal, in which are lodged the spinal chord, the origins of its nerves, and its membranous coverings. This canal, which is continuous with the cavity of the scull by means of the occipital hole above, and is completed by the sacral canal below, is not in the centre of the spine, nor is everywhere of the same dimensions. Situate behind the vertebral bodies, and before the spinal plates, it is nearer the posterior than the anterior region of the column. Large at the neck and upper part of the back, it diminishes below, and again enlarges in the loins. Its area is triangular in the cervical region, oval in the dorsal, and triangular again in the lumbar and sacral regions. It follows the different curvatures of the spinal column. In the recent state, it is formed not by the bones only, but before by the intervertebral cartilages, and behind by the yellow ligaments and the *interspinales* and *intertransversales* muscles. Lined by periosteum, by the posterior vertebral ligament, and by a quantity of loose cellular tissue, it is further covered by a cylindrical fibrous membrane, similar to the *dura mater*, the outer investment of the spinal chord; and within this are contained the *ligamentum denticulatum*, the spinal arachnoid, and the spinal chord itself, with its anterior and posterior nervous roots on each side, and its appropriate blood-vessels. In early life the soft parts predominate; and the canal and its component bones are then susceptible of much freer and more extensive motion than afterwards, when ossification is complete, and the fibro-cartilages acquire firmness.

In the human subject it may be viewed as a firm but flexible bony cylinder, which performs several functions at once. Resting on the sacrum, which is wedged immovably between the iliac bones, it supports the trunk in the erect position, and transfers to the sacrum, on which it rests, the weight of the head, the chest, and great part of the abdomen. In the vertebrated animals in general it incloses the spinal chord, one of the most essential and constant parts of the nervous system. In the several regions it forms a sort of posterior protecting wall to several important vital organs. Thus, in the neck it forms a posterior barrier to the œsophagus, the windpipe, and the great sympathetic. In the back it constitutes the posterior wall of the chest; and in the loins and pelvis it is the posterior wall of the abdominal viscera and the large vessels.

In answering these ends, it is important to remark, that the firmness and mechanical arrangement of the spinous processes are of essential service. Their imbricated arrangement renders it impossible for any foreign body to enter the vertebral cavity and injure the spinal chord, unless between the occipital bone and atlas, or between the atlas and axis; and even at these points much precision is requisite to enter the cavity. Between the axis and the third vertebra it is more difficult, and below this next to impossible, without breaking the spinous processes.

With this character of security and support, the vertebral column unites a high degree of flexibility. Though the degree of motion between each vertebra is trifling, yet between several it is considerable, and between the whole twenty-four it is multiplied to a great amount. The motions of which the vertebral articulations admit are those of flexion and extension, rotation, and lateral flexion. Of these, flexion is that which is most extensive; for in the anterior direction there is less impediment to the motion of the vertebræ than behind, where the spinous processes allow no great extent of motion, unless where the habit has been acquired in early life, before ossification is completed. The rotatory motion of one vertebra on another is small; but by combining the motion of several or of the whole column, it becomes so extensive that some individuals can turn the head and neck more than half round. That these motions are the passive result chiefly of the intervertebral cartilages and the articulations of the oblique processes, may be inferred from the fact, that when the former are ossified, or the latter ankylosed, the motions are much impaired generally, and wholly destroyed in the vertebræ affected.

The motions of the head on the atlas have been already shortly noticed. Those of the atlas and occipital bone on the axis are, though simple in effect, complex in mechanism. The motion, indeed, is limited to that of rotation; but this rotation is extensive. This is favoured by the horizontal position, and the large extent of the inferior articular processes of the atlas, and the superior ones of the axis, the looseness of the articular capsule, and the absence of spinous process in the atlas. The axis and its odontoid process becoming the fixed point, the atlas, and with it the occipital bone and scull, turn on the elliptical flat articular surfaces, and on the odontoid process. On the first they glide extensively, and in opposite directions, while the capsular ligaments are stretched. On the odontoid process the motion is more limited, and from right to left, and conversely; and in the latter variety of motion, the arch of the atlas before, and the transverse ligament behind, move on the anterior and posterior facettes of the odontoid process.

The anatomical construction of this articulation, however, which is so favourable to extensive motion, is attended with the disadvantage of facilitating the luxation of the atlas on the axis. Luxation, indeed, may be re-

Special Anatomy. The spine.

garded as produced by too extensive motion of these bones, in which the articular processes of the former vertebra abandon those of the latter, and instead of resting on them, are placed on the same plane, while the spinous processes are separated at least half an inch. It may be further observed, that the want of fibro-cartilages between these bones before, and of yellow ligaments behind, is favourable to displacement. The effect of this change of position on the spinal chord is obvious. While the one side of the atlas is thrust off the axis, the other is forced so near its body and articular process, that it compresses the spinal chord, and may occasion palsy or immediate death, by injuring the chord above the origins of the phrenic and intercostal nerves. The vertebral arteries at the same time undergo so much stretching, that the blood cannot move through them with the natural facility.

It is nevertheless probable that displacement rarely occurs without such injury to the ligaments as to allow more extensive luxation than that now noticed. The odontoid ligaments, or the transverse, may be ruptured; and in either case the odontoid process is allowed to slip backwards, and plunges into the chord, and destroys its texture almost instantly. These ligaments may be ruptured either immediately by sudden violence, or in consequence of previous disease. In such circumstances, the injury done to the spinal chord is followed by almost immediate death, in consequence of the influence of the phrenic and intercostal nerves being suddenly suspended. In the same manner, the insertion of a cutting instrument between the occipital bone and *atlas*, or between the latter and the *axis*, so as to divide partially or completely the spinal chord above the origin of these nerves, an operation known by the name of *pithing*, is followed by immediate death.

§ 2. *The Chest.* (*Pectus*, Στηθος, *Thorax*.)

The chest may be defined as an osteo-cartilaginous inclosure, of an irregular conoidal shape, flattened before, concave behind, and convex on the sides. Its upper extremity is truncated. Its basis is irregularly oblique. It consists of the *sternum* before, the twelve dorsal *vertebræ* behind, twelve ribs on each side, and twelve cartilages connecting the ribs and sternum.

The sternum or breast-bone.

The *sternum* (*sternum*, στερνον, *os pectoris*) is a symmetrical, oblong, flattened bone, broad above, narrow in the middle, broad below, and terminating in a point placed perpendicularly on the anterior of the chest. It presents two surfaces, an anterior and posterior, two extremities, an upper and lower, and two margins. (Plate XXIV. fig. 1.)

The anterior or cutaneous surface, covered by skin, the aponeurosis of the sterno-mastoid and large pectoral muscles, and periosteum, is marked by four transverse ridges at intervals of an inch, indicating the lines at which the separate portions of the bone were united. The posterior, internal, or mediastinal surface, is a little concave, occasionally marked by a longitudinal depression in its middle; also presents transverse lines, but rather indistinct; is covered in the middle by the mediastinal cellular tissue, above by the sterno-hyoid and sterno-thyroid muscles, and on the sides by the *triangulares sterni*.

The superior or clavicular extremity of the sternum presents three crescentic sinuosities; one on the middle, bounded on each side by an elevated peak, hollowed before and behind, and one on each side, incrusted with cartilage and synovial membrane. The first of these corresponds with the trachea on the inside, and has the sterno-mastoid muscle inserted on each outside. With the two lateral cartilaginous surfaces the sternal extremities of the clavicles are articulated. Between the two is the interclavicular ligament, and all round are the ligamentous fibres of the sterno-clavicular articulation. This upper extremity is about double the breadth of the bone at its middle. Below, the bone becomes narrow, and below the fourth ridge it seldom exceeds half an inch in breadth. Here it terminates in an appendage, which is generally named the pointed or ensiform cartilage (*cartilago mucronata, c. ensiformis*). The shape of this is by no means always the same. In some subjects it is a flat, thin, and pointed process, not always very firm, but more solid than cartilage; in others it is a flat thin bone, terminating in two thin hooked points. In some it is obtuse and perforated. In some it is thrust forwards, in others it is bent inwards, or towards the one side. To this process the aponeuroses of the *recti abdominis* are attached.

The margins of the sternum, which are generally about half an inch thick, present seven articular depressions crusted by cartilage. The first of these, in which the sternal extremity of the first rib is lodged, is, immediately below the clavicular depression, superficial and rounded. The others, which are situate at the ends of the transverse ridges, and receive the cartilages of the next six ribs, are deeper, angular, and surrounded by elevated margins, to which, in the recent state, the circumference of a capsular ligament is attached. In general, the seventh depression is formed partly on the sternum, partly on the ensiform cartilage; and the intervals between the depressions are smaller below than above.

The sternum is chiefly cancellated, light, and loose, with little density, and a thin crust of compact bone. In the fœtus and infant it consists of eight or nine square pieces, separated by transverse furrows, which, by the union of two, are easily reduced to seven, and afterwards to five. By the further union of two of these portions they are afterwards reduced to three; and in this state they remain so long in some subjects that Soemmering describes the sternum not as one bone, but as three. The first of these portions, which is uppermost, is irregularly heart-shaped, or rather octagonal, with the tracheal depression and the clavicular articulations above, the depression for the cartilage of the first rib on the side, and half of that for the second at its lower margin, where it unites with the second. The latter is merely the middle and longest portion of the bone, and is occasionally in three portions, separated at the costal depressions. The third or lower portion is the ensiform cartilage, the ossification of which renders the bone complete.

The ribs.

The ribs may be defined to be long, flat, irregular bones, with an irregular semicircular curvature, placed on each side of the chest, at intervals of an inch or less, between the dorsal vertebræ and the sternum. In general their number is twelve on each side, rarely eleven or thirteen. Of these, seven are connected with the sternum before by individual cartilages, and five are connected indirectly to the cartilage of the seventh, without attachment to the sternum. The former are denominated true or sterno-vertebral ribs (*costæ veræ*); the latter are styled false or vertebral (*costæ spuriæ, vel nothæ*).

Each rib varies in length, breadth, and the direction of its curvature. The upper ribs are the shortest, and most incurvated in proportion to their length. The middle ribs, or the fourth, fifth, sixth, and seventh, are the longest, and form curves of the largest circle. The false ribs, which diminish in length from the eighth to the twelfth, are the least incurvated, or form curves of the largest circle. It is chiefly from the middle set that the common characters of these bones should be derived.

Proceeding on this principle, we find that each rib may be defined as a broad, flat, longitudinal bone, not only in-

Special Anatomy. The ribs.

curvated, but twisted from the direction of its original curvature. Each rib has a vertebral extremity, a cartilaginous extremity, and a body. The vertebral extremity consists of a tuberculated angular head (*caput*), with two cartilaginous facettes united at an angular line for insertion in the intervertebral depressions with which they are articulated. In the first and twelfth, and sometimes in the eleventh, there is one facette only corresponding to the single vertebra with which these bones are connected. Immediately before the head the rib is contracted and rounded, so as to form a neck (*collum*), which varies from five to six or seven lines in length; and before the neck is a tubercle or process (*tuberculum*) divided into two portions, one internal, smooth, cartilaginous, and uneven, articulated with the transverse processes of the dorsal vertebræ; the other external, rough, giving attachment to the middle costo-transverse ligament. Anterior to the tubercle the rib is straight for about one inch, and rough by the insertion of the *sacrolumbalis* and *longissimus dorsi* muscles. Beyond this point, which is therefore named the angle (*angulus*), the rib begins to be incurvated circularly, and bent downwards, so that the surfaces, which were external and internal, become obliquely superior and inferior. To prevent confusion, however, they must still be distinguished in the same manner.

The outer surface of the rib, therefore, is convex, and forms the outer bend of the circle. Behind, it is covered by the *latissimus dorsi* muscle. The internal, which forms the inner bend of the circle, is convex above, and forms a concave hollow below, bounded by two sharp margins; one proceeding straight from the head forwards, till it is lost about three inches from the cartilaginous extremity; the other, more acute, from the tubercle, and following the curvature of the rib to about two inches from the same point. In this groove are lodged the intercostal artery, vein, and nerve. The internal intercostals are attached to the inner lip of the margin; the external to the outer. The upper margin of the rib is obtuse behind, where the external intercostals are inserted; but becomes acute and rough before, where the internal intercostals are inserted. The anterior or sternal extremity of the rib is broad and large, and terminates in an oval hollow, in which the cartilage is inserted. In advanced life, when the union between the rib and cartilage is intimate, this hollow becomes less distinct.

Besides these common characters of the ribs, several present peculiarities deserving notice.

The first rib is short, almost semicircular, and its direction is such that its broad surfaces are superior and inferior, not external and internal, as in the others. The head of this rib possesses only one large articular facette, corresponding with the first dorsal vertebra, sometimes one large one, and a minute one corresponding with a small space of the last cervical vertebra. Its neck is short and round, and its tubercle is identified with the angle which is wanting. The superior surface of this rib is highly important. From the head and tubercle extends a rough surface, in which are inserted part of the *scalenus posticus*, part of the *serratus magnus*, and the *scalenus medius*. Next to this is a smooth, deep depression, over which the subclavian artery passes; then is an eminence, to which the *scalenus anticus* is attached; afterwards a superficial hollow, in which the subclavian vein is lodged; and, lastly, a rough surface at the sternal or anterior end, for the subclavian muscle. The lower surface of the first rib is uneven and slightly rough, but without groove at its outer margin.

The second rib resembles the first in direction, having rather an upper and lower, than an external and internal surface. The head is angular and acuminated, and the neck contracted; and the upper surface is rough by the *serratus magnus*; but the lower surface, from the tubercle, begins to present an angle in the shape of an oblique surface, bounded below by a rough ridge, within which is the groove for the intercostal vessels and nerves. Anterior to this flat oblique surface the rib is twisted, and undergoes a change in direction. In the third the angle is not more distinct, and it is only in the fourth that this part is well marked. This character continues to the eleventh, when it becomes indistinct, and in which the tuberosity disappears, or at least is identified with the head, which has only one facette. The groove also is so short as scarcely to be observed. Lastly, the twelfth rib, which is often unconnected with the others by cartilage, is without tuberosity, groove, or angle, and has, like the first, only one facette at the head.

The costal cartilages.

The true ribs are connected to the sternum by means of broad rounded pieces of cartilage, variable in length and direction in different ribs. That of the first rib is very short, rather broad, and its direction, though oblique from above downwards, is more horizontal than that of the inferior ones. The angle at which it unites with the sternum is acute above, and obtuse below. It is often ossified in the adult. The second is nearly horizontal, and follows the direction of the rib to which it is attached. The next five are more oblique from above downwards, as the lower end of the sternum inclines forwards, and the corresponding ribs bulge towards the base of the chest.

Each of these cartilages, invested by perichondrium, is attached by a rough surface to the anterior end of the rib; while the other extremity, which is rounded and covered by synovial membrane, is lodged in one of the articular depressions of the lateral margin of the sternum, and secured in this situation by a capsular ligament, strengthened by anterior and posterior fibrous bands.

The anterior or outer surface of the thoracic cartilages is slightly convex, the internal or posterior surface flat, inclining to concave, lined by pleura and covered by the *triangularis sterni* muscle. The upper margin is concave, the lower convex, giving attachment to the internal intercostal muscles, which in this region fill the intercartilaginous spaces.

The cartilages of the five false ribs differ from those of the true, in not being articulated directly with the sternum. The cartilage of the eighth rib, after bending forwards and upwards, is attached to the seventh by a tapering point with a minute articular surface. The ninth cartilage is attached in a similar manner to the eighth, the tenth to the ninth, the eleventh to the tenth, and the twelfth is either attached in the same manner to the eleventh, or hangs free, though attached to muscles connected with the others. Hence the twelfth, and not unfrequently the eleventh, are denominated floating ribs. The whole of them are mutually connected by ligamentous fibres inserted into their perichondrial covering. The outer surface of these cartilages is covered by the *recti* and external oblique, the inner surface by the diaphragm and *transversus*.

Connected with the ribs in the same manner in which those of the true ribs are, these cartilages differ, however, in taking a direction, first of descent, then of ascent or of curvature. The spaces which they leave between them, instead of being rhomboidal, as those of the true ribs, are irregularly triangular.

In structure the costal cartilages belong to those of the cavities. Analogous to those of the larynx, they are dense, firm, elastic, whitish substances, without distinct traces of organization, and seem to consist chiefly of modified gelatine, to which they are with difficulty reduced by

Special Anatomy.

long boiling. Their tendency to ossification is considerable. In few persons above 45 or 50 are they quite free from bony points; and in many they are at this period converted into firm bone. The cartilage of the first rib, especially, is often firmly ossified before 35. When they undergo this change, certain points in their substance are observed to assume an orange or tawny colour, and to exhibit a porous arrangement, with great hardness, turning the edge of the knife.

By long maceration the costal cartilages become soft and gelatinous, and are finally resolved into oval patches, separated by circular or spiral lines, with numerous perforations. It was perhaps on this account that Herissant described them as consisting of spiral fibres.

The chest in general.

The bones and cartilages now described, with the twelve dorsal vertebræ behind, constitute the bony skeleton of the chest, bearing a remote resemblance to a cone, with truncated apex and oblique base, or, more accurately, to the frustum of a cone. To form a just idea of this assemblage of parts, it is necessary to consider its surface external and internal, its circumference above and below, its transverse diameter, and its longitudinal extent.

The anterior region of the external surface, consisting of the sternum in the middle, and the cartilages on each side, is flattened, contracted above, wider and more prominent below. The intercostal spaces are filled between the sternum and the ribs by the internal intercostals, behind this by the external and internal, and covered by the anterior part of the large pectoral muscle. Behind, the chest presents the vertebræ with their processes, the transverse processes articulated with the tubercles, the angles forming a line obliquely receding from the spine, the transverse grooves, the longitudinal groove on each side filled by the *multifidus spinæ*, and the space between the processes and the angles of the ribs occupied by the *spinalis dorsi*, the *longissimus dorsi*, and the *sacrolumbalis*. The intercostal spaces, from the spine to the angles, are filled by the external intercostals; and anterior to this are the two layers of muscles.

The lateral regions of the chest are convex, making a larger sweep below than above. They present on each side eleven intercostal spaces, the superior of which are shorter and broader than the inferior. These spaces, which follow the curved direction of the ribs, cannot be accurately defined in shape. Between the angles and the cartilages, where the curvature is greatest, they are occupied by the double layer of the external and internal intercostal muscles, which, lying inclined in opposite directions, mutually decussate in this tract. The lateral region of the chest is covered above by the *serratus magnus* behind, and the two pectorals before; below by the external oblique on the side, and the *recti* before. The inferior lateral region, which is formed by the cartilages of the ribs, is therefore named the hypochondres (*hypochondria*).

The inner surface of the chest is, before, correspondent to the outer surface, unless below, where the anterior inclination of the sternum makes the antero-posterior diameter greater. The posterior region is marked by the row of vertebral bodies, the prominence of which forms an imperfect partition, which separates the right and left halves of the thorax; and which, notwithstanding the posterior bend which the spine undergoes between the second and eighth vertebræ, diminishes the antero-posterior diameter of the chest. On each side is a large concave hollow, narrow above, wide below, and swelling most capaciously in the middle, the walls of which, formed by the ribs and intercostal muscles, are lined by the pleura, and the cavity of which contains the lungs.

The upper circumference of the chest, or its apex, is small, oval, transversely oblique from above downwards, and from behind forwards. Bounded before by the sternum, behind by the first dorsal vertebra, and on the side by the first rib, it is diminished by the clavicles; and while its antero-posterior diameter is occupied by the windpipe, œsophagus, and the large vessels connected with the heart, its lateral portions are so much contracted, that each thoracic half (*demithorax*) has here almost a conical termination. Its dimensions in the male skeleton of average size are about 16 inches. As the first rib has little or no motion, the upper circumference remains unchanged.

The lower circumference of the chest, which is much more extensive, is said to be nearly four times larger than the upper. This, however, is exaggerated; and I find its greatest dimensions in the male to be 32 inches, exactly double the small circumference. It is susceptible of enlargement from the revolving motion of the ribs. The first rib remains fixed, while the lower ones are capable of being rolled outwards on their heads, tubercles and cartilages, so that the transverse diameter of the chest is enlarged. The lower circumference of the chest presents anteriorly a large triangular notch (*incisura trigona*), with the apex at the ensiform cartilage, the sides at the margins of the cartilage, and the base represented by a transverse line uniting the tips of the twelfth rib on each side. This notch, which, in the recent state, is occupied by the heads of the *recti* muscles, with their fasciæ in the middle, and the anterior margins of the external oblique at the sides, constitutes what is called the pit of the stomach (*scrobiculus cordis*), or the epigastric region (*epigastrium*).

The transverse diameter of the chest is small above, but gradually enlarges to the ninth or tenth rib. The average diameter measured between the inner margins of the first ribs on each side in the male skeleton is four and a half inches; the average diameter measured between the tips of the eleventh rib on each side is nine inches, which is also nearly the diameter between the inner margins of the fifth ribs; and the average diameter measured across the upper margin of the ninth rib, which is about the widest part, amounts to eleven inches. These diameters, it has been already said, are susceptible of slight enlargement, by reason of the lateral revolution of the ribs; and this motion is most extensive between the sixth and tenth ribs. Above the sixth and below the tenth it is trifling.

The longitudinal extent or altitude of the chest varies, but in the same male skeleton it amounts to twelve inches measured between the lower margin of the first rib and the upper margin of the eleventh, which may be regarded as the inferior limit of the osseous part of the chest. From the top of the sternum to the plane of the ensiform cartilage the distance is five inches and a half. If from the lower margin of a mesial plane representing the *mediastinum*, another plane be drawn on each side to the margins of the false ribs, the space inclosed on each side above this oblique plane will give some idea of the capacity of the thoracic cavities.

The dimensions above stated apply chiefly to the adult male, from about thirty to thirty-five years, and of average size. In the female the chest is generally smaller in every direction, rounder, and more taper towards its inferior region. Above, as far as to the fourth rib, it is said to be larger and more uneven before, so that it has less of the conoidal shape than the male chest. It is also shorter.

The pectoral cavity is in general symmetrical, that is.

Special Anatomy.

of similar shape and dimensions on each side of the mesial plane. Sometimes, however, without the intervention of disease, the greater convexity of two or three ribs on one side gives it a more ample appearance than on the other.

§ 3. *The Pelvis.*

This is the name given to the irregular-shaped bony cincture which terminates the lower extremity of the trunk, and which is connected to the spinal column by means of the sacrum. It consists in the adult of four bones, two lateral portions (*ossa coxarum*), and two on the mesial plane, the *sacrum* and *os coccygis*. The latter two have been already described. The lateral and anterior divisions now come under examination.

These consist of two bones, one on each side, united with each other before by means of fibro-cartilage, and receiving between them behind, the sacrum, to which they are in like manner united by fibro-cartilage. These bones, which are denominated *ossa innominata*, coxal or haunch-bones (*ossa coxarum*), are of a very irregular shape, and may be divided into three regions, the superior or iliac, the anterior or pubal, and the inferior or ischial. These regions it is not easy to define accurately; but they will appear in the course of description, and they correspond to the original divisions of the bone in the fœtal state.

The coxal bones.

The coxal bone presents two surfaces, an external or femoral, and an internal or pelvic; and a circumference, divided into superior margin, anterior margin, inferior margin, and posterior margin.

The external or femoral surface (*dorsum*), which is alternately concave and convex, presents behind a rough surface, to which the *glutæus maximus* is attached; between this and a semicircular rough line a lunated hollow, in which the origin of the *glutæus medius* is lodged; and between the upper semicircular line and the lower a convex and concave area, for the attachment of the *glutæus minimus*, and one or two inequalities, to which one of the tendons of the *rectus femoris* is attached. About an inch below is a large hemi-spherical cavity, with elevated circular margins, interrupted at the anterior and inferior corner, named the *acetabulum*, or cotyloid cavity, for receiving the head of the thigh-bone. Its inner surface is covered by cartilage, unless at the centre, where is a depression for the attachment of the triangular ligament of the thigh-bone. The lower part of the margin is marked by a deep notch, over which, in the recent state, is stretched a ligament, thus forming a hole for the transit of the vessels and nerves of the articular cavity. The surface behind the acetabulum is slightly convex, indicating its union with the upper edge of a part of the coxal bone, distinguished by the name of hip-bone (*os ischii*), and may be denominated the *post-acetabular* or *ilio-ischial eminence*; below, it is concave and sinuous, for the tendon of the *obturator externus*, and terminating in a sharp spine (*spina ischii*), to which the small sacro-sciatic ligament is attached. Anterior to the acetabulum is a large opening, named the *thyroid* or *obturator* hole, oval in the male, and triangular in the female, closed by a ligament attached to its circumference, unless at the upper part, where there is an oblique groove for the *obturator* vessels and nerve. The outer surface of the thyroid ligament supports the *obturator externus* muscle, the inner surface the *obturator internus*. The upper margin of the thyroid hole is overhung by a convex ridge of bone, which is named the pubal or the horizontal branch of the pubal bone (*os pubis, pecten, os pectinis*) from supporting the parts of generation, and which terminates at its inner or mesial margin in a spine or tubercle, to which the outer portion of the tendon of the external oblique muscle is attached. The inner or anterior margin of the thyroid hole is bounded by a broad flat bone, irregularly rough on the surface, broad above, where it is connected with the *os pubis*, narrow at the middle and lower part, where it joins the ischial bone. To the upper part of this, which is named the descending branch (*ramus*) of the pubis are fixed the *gracilis*, the head of the *adductores longus et brevis*, part of the *adductor magnus*, and part of the *obturator externus*. The lower part, which is named the ascending branch (*ramus*) of the *ischium*, gives origin to the *adductor magnus*.

Special Anatomy.

The coxal bones.

The inner or pelvic surface (*venter*) of the coxal bone may be divided into three parts. The first is posterior, rough, and irregular, for articulation by fibro-cartilage with the lateral margin of the sacrum. The second, which is abdominal, concave, and is named the iliac pit (*fossa iliaca*), contains the belly of the *iliacus internus*, bounded above by the circumference or crest of the bone; behind by a rough line which separates it from the sacral surface; before by a concave irregular bend formed above by the iliac, below by the pubal bone; and below by a sharp line (*linea ilio-pectinea*), which is insensibly lost on the spine of the pubis, and to the inner end of which is attached a reflected portion of Poupart's ligament, named the *ligament of Gimbernat*. The third or pelvic surface, which is below, presents behind a flat, irregular-shaped, concave space, occupied by the *levator ani* and part of the *obturator internus*, the inner opening of the thyroid hole, the inner surface of the *rami* of the pubal and ischial bones, with inequalities for the origin of the *obturator internus*, and a sinuosity below the ischial spine for the motion of its tendon.

The circumference of the coxal bone is very irregular. The upper or iliac portion, which is semicircular, and is named the crest (*crista ilium ossis*), is rough for muscular and tendinous attachments, varying in breadth from half an inch to a whole one, and is distinguished into an external and internal lip, and an intermediate space. To the former are attached the external oblique, the *latissimus dorsi*, and the *tensor vaginæ femoris*; to the latter are attached the *transversus* and the *quadratus lumborum*; and in the middle space between the two is the internal oblique. The posterior end of the crest terminates in the posterior superior spinous process, to which part of the *glutæus maximus* and the ilio-lumbar ligament are attached, and below the posterior inferior spinous process forming the upper extremity of the ischiatic notch. The crest terminates before in the anterior superior spinous process, to which are attached the *fascia lata*, the *sartorius*, and the upper end of the tendon of the external oblique, or ligament of Poupart, or what is named the crural arch. The anterior portion presents, first a small sinuosity, which separates the superior from the inferior spinous process, to which is attached the upper tendon of the *rectus cruris*. Between this and an eminence in the upper or horizontal portion of the *os pubis*, marking its junction with the iliac bone, and which may be denominated the *ilio-pubal*, is a large sinuosity, in which are lodged the tapering ends of the *iliacus internus* and *psoas magnus*. To the ilio-pubal eminence the *psoas parvus* is attached; and within the pubal eminence, and anterior to the *linea ilio-pectinea*, is a triangular space, to which the origin of the *pectineus* is fixed. This part of the circumference is terminated by the spine of the pubal bone, to which the first insertion of Poupart's ligament, or the outer pillar of the inguinal ring, is fixed. On the mesial side of this is a rough tubercular surface, which by means of fibro-cartilage is united with a similar surface on the opposite side. To this, which is named the *symphysis pubis*, the second insertion of the ligament of Poupart, the *pyramidales* and the *recti*, are fixed.

Special Anatomy.

The coxal bones.

The posterior-inferior margin is most irregular. Commencing with the posterior spinous processes, which are parted by a small notch, the margin is, immediately anterior to the lower process, formed into a large hollow, named the ischiadic notch (*incisura ischii*), bounded before by the spine of the ischium, to which is attached the anterior sacro-ischiadic ligament, with the superior head of the *gemellus* without, and the *coccygeus* within. A pretty large hollow, in which play the belly and tendon of the *obturator externus*, separates the spine from the tuberosity of the ischium, a large broad rough surface, the external surface of which gives support to the *quadratus* and *adductor magnus*, the inner surface to the lower head of the *gemellus* and the external or inferior sacro-ischiadic ligament, while in the middle are fixed the long head of the *biceps flexor*, the *semitendinosus*, and the *semimembranosus*. From the tuberosity the margin of the bone along the ascending branch of the ischium, and the descending branch of the pubis, becomes narrow till it reaches the *symphysis*, when it again becomes broad and more irregular. To the former margin are attached the *gracilis*, the *transversus perinæi*, the *erector*, and the *corpus cavernosum*. The latter uniting with the opposite bone by means of the interpubal fibro-cartilage, constitutes the *symphysis pubis*.

Structure.

The iliac or coxal bones consist of cancellated matter, covered by a thin layer of compact bone. In early life, and in delicate subjects, this cellular matter is loose, abundant, and rather thick. At a more advanced period, when ossification is completed, and in strong muscular subjects, the proportion of this cancellated matter diminishes and sometimes disappears, so that the bone consists of two layers of dense, compact bone; and in some, even this, in the iliac fossa, is destroyed entirely, so that the bone appears perforated.

Developement.

The coxal bone is formed originally of three pieces, one for the large upper portion (*os ilium*), a second for the anterior or pubal (*os pubis*), and a third for the inferior or ischial (*os ischium*). In the fœtus, infant, and young subject, these three bones are seen quite distinctly separate, but adhering, by means of fibrous or fibro-cartilaginous tissue, along a line drawn by the ilio-pubal eminence through the acetabulum, and over its posterior convexity into the ischial notch. At the same time the crest and margins of the ilium are covered by a cartilaginous epiphysis; the pubal bones are mutually attached by the same substance; the branches (*rami*) of the pubal and ischial bones are soft and membranous; the thyroid hole is merely a ligamentous notch; and the acetabulum is a broad, irregular, superficial depression, with fibro-cartilaginous margin. The connections of these three bones continue soft and cartilaginous for several years after birth, generally to the tenth, twelfth, or fourteenth, sometimes later; and this is the reason why the *os innominatum* has been described as consisting of three bones, the *os ilium*, *os pubis*, and *ischium*. After the last-mentioned period, however, these bones are firmly consolidated into one piece, in which, nevertheless, the original marks of separation may be recognised in the ilio-pubal and post-acetabular eminences above, and the meeting of the pubal and ischial *rami* below. The coxal bone, therefore, which thus becomes a single solid piece in the adult, ought to be always described as such; and the distinction into three component parts, which is confined to the fœtal and early period of life, belongs to the history of its ossification.

The coxal bone is united to its fellow of the opposite side by the *symphysis pubis*, and behind to the sacrum by the sacro-iliac fibro-cartilage (*synchondrosis*). Both of these junctions are occasionally ossified in advanced life. By the cotyloid cavity it is articulated with the head of the thigh-bone.

The pelvis generally and its dimensions.

The coxal bones on each side, with the sacrum wedged between them behind, and the os coccygis attached to its extremity, constitute an irregular-shaped osseous cincture, something conical, with the base above, and the truncated apex below. This shape, with the manner in which it supports the abdominal viscera and several of the urinary and genital organs, has given it the name of basin (*le bassin*, *das becken*, *pelvis*) or pelvis. In this it is requisite to consider the external and internal surface, the upper and lower circumference, the transverse diameters, the direction, the outlets and their dimensions.

The external surface comprehends four regions, the anterior or pubal, the posterior or sacral, and two lateral.

The anterior region presents the pubal articulation (*symphysis*) on the median line, and on each side the pubo-ischial *rami*, the thyroid hole and its margins, and the *acetabulum* or articular cavity. The posterior region presents on the median line the sacral spinous processes or spinous ridge, the triangular depression which terminates the spinal canal, the suture uniting the sacrum to the coccyx and the posterior convex surface of the latter; and on each side are the sacral grooves and posterior holes; the processes by which they are bounded without; a deep depression corresponding to the sacro-iliac *synchondrosis*, and which is filled by a thick bundle of ligamentous fibres; and lastly, the posterior tuberosity of the ilium, which projects much behind. The lateral regions are formed by the *dorsa* or external *fossæ* of the iliac bones, bounded below by the ischiadic notches.

The internal surface of the pelvis consists of two portions,—the one above, wide, capacious, and tapering downwards, forming the large pelvis; the other narrower, with walls nearly cylindrical, and forming a canal named the small pelvis.

The large pelvis presents, behind, the sacro-vertebral articulation and the sacral promontory, and on the sides the internal iliac *fossæ*. Before, where osseous parietes are wanting, the space is occupied by the abdominal muscles. This constitutes the abdominal division of the pelvis, and supports in the erect position part of the ileum and colon. Its transverse diameter, measured between the crests of each iliac bone, amounts to nine inches in the male, and eleven in the female.

The large or abdominal division of the pelvis is bounded below by the ilio-pubal line on the sides and front, and behind by a line drawn between the posterior extremities of each side, but following the surface of the sacrum. The outline of this, which is elliptical, with the transverse diameter longest, and its plane inclined obliquely forwards, is named the superior outlet or aperture (*ambitus superior*) of the pelvis, and it constitutes at once the lower termination of the great and the upper boundary of the small pelvis. Its importance in the practice of midwifery renders it necessary to distinguish its calibre, which is larger in the female than in the male, into four diameters. The first, antero-posterior, from the pubal symphysis to the sacral promontory, is from four to five inches in the male, and four inches nine lines in the female. The second, transverse, measured between the iliac bones, is four inches six lines, sometimes five inches, in the male, and five inches six lines in the female. Two others, drawn obliquely from the sacro-iliac synchondrosis to the ileo-pubal eminence, are about four and a half inches in the male, and five inches in the female.

The small or proper pelvis, which is below this aperture, forms a sort of cylindrical osseous canal, more capacious,

Special Anatomy.

The pelvis generally, and its dimensions.

however, at its middle than at the extremities, the lower outlet of which is diminished by the anterior incurvation of the sacrum and coccyx, while the sides are bounded by the ischio-pubal branches. Before are the inner surfaces of the pubal symphysis and branches, corresponding to the urinary bladder; behind, the pelvic surface of the sacrum, corresponding to the rectum; laterally, the thyroid holes, the inner surface of the ischial-bone and ilio-ischial junction, and the ischiatic notch, completed by the anterior and posterior sacro-ischiatic ligaments.

The upper circumference is very irregular, with its plane slightly inclined forwards; larger in the female than in the male. It presents, behind, the sacro-vertebral articulation, bounded by a depression indicating the upper edge of the sacro-iliac synchondrosis; laterally, the two iliac crests terminating before in the anterior superior spinous processes; before, the hollow of the *iliacus internus* and *psoas magnus*, the ilio-pubal eminence, the horizontal branch of the pubal bone, its spine, and lastly its symphysis.

The lower circumference, which corresponds with the inferior aperture or ano-perineal outlet of the pelvis (*ambitus inferior*), is directed downwards and backwards. Bounded behind by the coccygeal bone, and on the sides by the ischial tuberosities, this outlet is thus distinguished for three eminences, separated by an equal number of notches. The situation of these eminences indicates the limits of the lower pelvic aperture. The size and disposition of the notches is inversely to that of the eminences; and their arrangement is such that an eminence is opposite to a notch, and conversely. Thus the anterior notch, which is formed by the pubal arch, is opposite to the sacro-coccygeal eminence behind; and though the ischial tuberosities appear opposite to each other in one sense, strictly speaking their plane is each accurately opposed to the opposite sacro-ischial notch. The anterior notch is terminated above by an acute angle in the male, in consequence of the proximity of the pubo-ischial branches which form its sides, but by a rounded arch in the female, by reason of the separation of these branches on each side. In this notch are situate the generative organs of both sexes. The lateral notches, which are bounded behind by the sacrum and coccyx, before by the spine and tuberosity of the ischium, are irregular in shape, and are each subdivided into three portions by the sacro-sciatic ligaments, which secure the articulation of the sacrum and coxal bones. The first of these ligaments, the posterior or external, arising from the posterior extremity of the iliac crest, from the sides and transverse processes of the sacrum and coccyx by a broad, firm web of fibres, becoming small and thick at the middle, again expands, and is inserted into the ischial tuberosity. This ligament corresponds behind to the *glutæus maximus*, which is partly attached to it, before and mesially to the small or anterior ligament to which it is united. The small or anterior sacro-sciatic ligament rises, in common with the large one, from the transverse processes of the sacrum and coccyx, and adhering to it for half an inch, passes more horizontally outwards to the ischial spine, in which it is implanted by a broad, thick, fibrous web. Behind, it corresponds at its sacral end, and for an inch from this to the posterior ligament, and laterally to the pudic vessels and nerve; before, it serves with the posterior to complete the lower circumference of the pelvis.

By these two ligaments the ischiadic notch is in this manner converted into two apertures and a notch. The first of these is superior, and is bounded above by the ilio-ischial arch, and below by the small ligament and part of the posterior or large ligament. Through this hole pass the *pyriformis*, the sciatic nerve and artery, the gluteal artery, and the internal pudic artery. The second is an irregular triangular hole, smaller than the upper one, bounded above by the anterior ligament, below by the posterior one, and laterally by the sinuous hollow between the ischial spine and tuberosity. Through this aperture the tendon of the *obturator internus* passes out of the pelvis; and the external pudic artery and nerve, after bending round the upper ligament, re-enter the pelvis. The third space is a superficial notch, bounded on the outer or lateral side by the posterior ligament, and on the mesial side by the sacro-coccygeal bone. It is chiefly occupied by cellular tissue.

The dimensions of this inferior aperture are nearly the following. The antero-posterior diameter, from the coccygeal apex to the lower margin of the pubal symphysis, is 3 inches in the male, and 4 inches 6 lines in the female. The transverse diameter between the ischial tuberosities of each side is 3 inches 2 lines in the male, and 4 inches in the female. The oblique diameter, measured from the middle of one of the great sacro-sciatic ligaments to the opposite ischial tuberosity, is about 4 inches in the male, and from $4\frac{1}{2}$ to 5 in the female. Of these diameters the antero-posterior is most liable to vary, by reason of the mobility of the os coccygis; but independent of this, it is always larger in the female than in the male, in consequence of the sacrum being less incurvated, and descending more in a straight line. It further appears, that in females who have born children the incurvation of the sacrum is much less than in those who have not.

The direction of the pelvis is not horizontal, nor does it correspond with that of the trunk. Articulated behind with the lumbar portion of the spinal column, the axis of which is inclined considerably forward from the vertical plane, the pelvis partakes of the same inclination. A horizontal line drawn from the pubis towards the sacrum passes in general an inch below the tip of the coccyx; and with this a line drawn from the pelvis to the upper margin of the sacrum, representing the plane of the pelvis, makes an angle of between 80° and 85°. The sacrum inclines from the vertical plane about 35°; but the inclination of the superior and inferior pelvic apertures varies. An imaginary line drawn from the tip of the coccyx to the centre of the small pelvis, to represent the axis, cuts the line of inclination at an angle of 75°. The most accurate axis of the pelvis is a line drawn at right angles to the plane of the pelvis as above found.

The dimensions given above are sufficient to show that the female pelvis is much more capacious and ample laterally than the male. In the female, indeed, it is important to remark that the upper region of the coxal bones is more prominent laterally, and hence renders the haunches prominent and rounded, and the outline of the abdominal aperture more extensive; the sacro-vertebral angle is less prominent, and the sacrum is broader and less incurvated; the arch of the pubis is wider and less angular; the ischial tuberosities are more apart, and the cotyloid cavities even are at more distance from each other,—a circumstance which determines the peculiar gait of the female. The male pelvis, on the contrary, is deeper than the female.

In the infant the pelvis is small compared with the size of other bones, and of the parts which it is to contain. The dimensions of this part, in early life, are indeed so limited, that not even the urinary bladder can be said to be contained within it. As puberty approaches, the distinctive characters of the male and female pelvis begin to appear. While in both sexes the bones become larger and the cavity more capacious, in the female the addi-

Special Anatomy.

The head.

tional amplitude appears in the width of the haunches, and their remarkable projection beyond the flanks.

The Head.

The upper or atlantal extremity of the vertebral column supports the head, a complicated assemblage of bones, the general shape of which is spheroidal above and behind, and irregularly cubical before and below. It is naturally divided into two parts, which are distinguished by their mechanism, their use, and the mode of their developement. The first of these, the scull or cranium (*κρανιον, calvaria*), forms a spheroidal bony case, occupying the superior and posterior region chiefly of the head. The second, which is the face, is formed above by an irregular pile of bones, articulated immovably to the anterior inferior part of the scull, and below by a single symmetrical bone, articulated movably to the middle of the lower part of the scull.

§ 4. *The Scull.* (*Cranium, Calvaria.*)

The scull.

The scull consists of eight bones, four of which are symmetrical and arranged on the mesial plane, and four arranged in pairs on each side. The four symmetrical bones are the frontal, the ethmoid, the sphenoid, and the occipital; the four lateral are the two parietal and two temporal bones.

The frontal bone.

The frontal bone (*os frontis, os coronæ, sinciput*) is a symmetrical bone occupying the anterior part of the scull, and forming the anterior part of the scalp and the part of the face distinguished as the brow (*frons*). It may be divided into three surfaces, the external or frontal, the inferior or orbito-ethmoidal, and the internal or the cerebral, and a circumference. The external surface is frontal and temporal.

The frontal surface, which is convex and regularly arched, presents on the median line a ridge, indicating the original separation of the bone in two halves, the nasal protuberance, more convex in age than in youth; and corresponding to the smooth interval between the eyebrows (*glabella*), a serrated margin articulated in the middle with the nasal bones, on the sides with the ascending processes of the superior maxillary bones, and, lastly, the nasal spine, which supports the nasal bones. (Plate XXV. fig. 2. n.)

On each side of the median line are the large smooth surface of the upper part of the frontal bone, the frontal protuberances (*tubera frontis*), large in youth, small in advanced age; the superciliary arch (*supercilium*), an irregular convexity extending transversely about an inch on each side of the mesial line, most prominent within, where the *corrugator supercilii* is fixed; and, lastly, the orbitar arch, large and prominent at its temporal angle, smaller and more rounded at its nasal, and presenting either a hole, or a notch covered by a ligament (c. c.), and through which pass the frontal artery and nerve. The nasal end of the orbitar arch, sometimes named the *internal angular process*, is insensibly lost in the serrated surface, where it joins the superior maxillary bone. The temporal process, which is prominent, terminates in a serrated surface, which is articulated with the malar bone. Exterior to the frontal protuberance is a curvilinear ridge (d.), which gives attachment to the fascia of the temporal muscle, denotes the anterior boundary of the space in which that muscle is lodged, and separates the proper frontal from the temporal surface of the frontal bone. This ridge, descending in a circular direction, terminates in the temporal process at the opposite side to that of the orbital arch (a. a.) The triangular segment cut off by it is convex above and concave below.

Special Anatomy.

The frontal bone.

The orbito-ethmoid surface is irregular. It presents first on the median line a quadrilateral notch with serrated margins, in which the ethmoid bone is articulated. These margins consist in adult subjects of two plates, between which are seen segments of the frontal and ethmoidal sinuses. In the outer of these tables are generally one or two holes, or notches, which, with the ethmoid bone, form holes (*foramen orbitarium internum anterius et posterius*). Through the former pass the ethmoidal twig of the nasal branch of the ophthalmic nerve; through the latter the posterior ethmoidal artery and vein. On each side of the ethmoidal groove is a triangular concave surface, which forms the vault of the orbit, near the outer margin of which, and within the external angular process, is a superficial pit for the lacrymal gland, and towards the nasal side a depression for the reflected tendon of the superior oblique muscle.

The internal or cerebral surface, which is concave, covered by the *dura mater*, presents on the median line a groove, the beginning of the sagittal, in which the superior longitudinal sinus is lodged, and the margins of which, converging below, form a crest corresponding to the upper margin of the falx. Below this is the *foramen cæcum*, which in the bone communicates with the two canals belonging to the nasal bones, but in the recent state allows some veins to pass from the nose to the longitudinal sinus. It is sometimes common to the frontal and ethmoid bones. (Plate XXV. fig. 3. c.)

On each side the frontal bone presents the large cavities, in which are contained the anterior extremities of the hemispheres of the brain; and above these the bones rise in the manner of a vaulted arch. The whole inner surface is moulded into alternate pits and eminences, called *digital* and *mammillary* respectively, and which correspond to the eminences and depressions of the cerebral convolutions. These are most conspicuous at the lower part, where the surface is traversed by minute vascular grooves.

The circumference of the bone is serrated all round, for articulation with the contiguous bones. The posterior margin is nearly of an elliptical outline, straight, and interrupted below by the quadrilateral notch. Above, where the frontal is articulated with the parietal bones, the serrated processes proceeding from the outer table are largest and longest. Below, where the frontal is articulated with the lower angle of the parietal and wing of the sphenoid bone, the internal table is most prominent, so that the spheno-parietal suture is imbricated. Between the temporal and orbitar fossæ this separation of the tables forms a triangular rough surface, which is articulated with a similar one, the triarcual surface of the sphenoid bone; and between this and the quadrilateral notch the margin is articulated in the same manner with the anterior margin of the sphenoid bone. Lastly, the serrated and cellular margins of the quadrilateral notch are connected with the ethmoid bone.

Besides these cranial bones, the frontal is articulated with the following bones of the face,—the nasal bones by the middle of the nasal suture, the superior maxillary bones by its sides, the lacrymal bones by the anterior end of the ethmoidal groove, and with the malar bones by the external angular processes.

The frontal bone, which is thick at the nasal protuberance and the external processes, and thin at the orbitar regions, is ossified by two points, which, appearing at the frontal protuberances, proceed by radiation as from a centre towards the circumference of the bone. In the fœtus and early infancy the bone thus consists of two lateral portions placed between the pericranium and *dura mater*,

Special Anatomy.

The frontal bone.

with a longitudinal interval on the mesial plane, a transverse one on the site of the coronal suture, and a triangular chasm at the angle between the two. This chasm, with a similar one between the frontal bones, forms a quadrilateral lozenge-shaped space, at which the motion of the brain is distinctly felt both at birth and for months after, and which is therefore named the *fontanelle*, or the anterior *fontanelle* (*fons pulsatilis; bregma*), or the open of the head. As the ossific process advances, the lateral margins of the bone extend, and the mesial margins extending mutually, at length coalesce, first at the nasal protuberance and along the forehead, afterwards above, until the fontanelle is progressively diminished and at length obliterated. This junction is effected by the formation of serrated processes, which are mutually dove-tailed into each other; and for some years after birth the frontal bone consists of two similar halves articulated by a middle suture. In some few instances, especially in the female, this continues for many years; and the individual is found after death to have the frontal bone in two halves, with a middle suture. More frequently, however, the suture is obliterated by the consolidation of its serrated margins, and the frontal bone consists of one piece. The points of ossification remain long distinct in the form of the frontal protuberances. But eventually, from the uniform elevation of the margins of the bone, they become less conspicuous; and in old age they disappear more or less completely, leaving a surface uniformly uneven.

The ethmoid bone.

The ethmoid or sieve-like bone (*os cribriforme*), which is symmetrical, and occupies the quadrilateral notch of the frontal bone, consists of several bony plates arranged at right angles, and parallel with each other, so as to give the whole a cubical shape. It consists of four parts, a horizontal plate, occupying both sides of the mesial plane; a vertical plate at right angles to it, and corresponding with the mesial plane; and a lateral plate on each side, also vertical and parallel to the middle plate. In the bone thus formed the following circumstances deserve attention. (Fig. 5.)

The superior surface, cerebral, covered by *dura mater*, is formed by the horizontal plate, perforated by numerous holes (*lamina cribrosa*), through which pass the fibrils of the olfacient or first pair of nerves depressed longitudinally on each side, but surmounted in the middle towards its anterior half by a strong process of a triangular shape, named the cock's comb (*crista galli*), and to which is attached the anterior inferior extremity of the falx, or dichotomous membrane. The anterior margin of this process is generally marked by a groove which, with that of the frontal bone, forms a passage for the nasal vein into the longitudinal sinus. The posterior margin of the perforated plate is marked by an angular notch between two horns, for articulation with a salient angle of the sphenoid bone. The *crista galli* may be regarded as the upper division of the vertical plate, which occupies the mesial plane, and which is thick and sometimes bifid before, but thin and rough behind, where it acts as a partition to the lateral halves of the ethmoidal cavities. The sides of this middle vertical plate are furrowed by minute canals (*canaliculi*), traced from the *foramina* above, in which the nervous fibres are lodged. This plate, and indeed the lower surface of the perforated plate, are covered by a fibro-mucous membrane, which has been named the pituitary or the Schneiderian. The vertical ethmoid plate is articulated at its lower margin with the *vomer* and the triangular cartilage of the nose, before with the nasal spine of the frontal bone, and behind with the median crest (*processus azygos*) of the sphenoid bone.

The lateral portions of the ethmoid bone consist externally of a smooth flat bone (*os planum* of the ancients), which forms the inner or nasal wall of the orbit, internally of two bones convoluted on themselves, and which are distinguished as the superior and middle turbinated bones (*conchæ, ossa turbinata superiora et media, ossa spongiosa*). These bones are seen most distinctly behind; but to form a correct notion of their figure, it is requisite to detach the lateral portions and examine them separately, when the following peculiarities may be recognised. The *ossa plana* on each side terminate in concave oblong quadrilateral plates, diverging outwards from the vertical plane. At the internal edge of these quadrilateral plates is seen above a convex bone, with numerous minute perforations, the orifices of short canals. This is the superior turbinated or spongy bone. Below, and a little to the external side, is a small groove, separated by a thin plate from a larger cavity, which is the superior *meatus*, leading into the posterior ethmoid cells. Below this, again, is the osseous plate, with perforated edges turned on itself from within outwards, so that its convex side is towards its fellow, and its concavity is below and laterally, and separated by another thin plate from the lower margin of the *ossa plana*. This is the *middle turbinated bone*, the longitudinal cavity of which communicates with the lower or nasal surface of the bone, and is bounded on its outer margin by the lower margins of the *ossa plana*, where they are articulated with the inner margin of the orbitar plate of the maxillary bone. The anterior deficiency of the *ossa plana* is occupied by the lacrymal bones.

Special Anatomy.

The ethmoid bone.

The internal surface of these bones generally is covered by a thin fibro-mucous membrane, partaking of the characters of periosteum at its attached, and of mucous membrane at its free surface.

The ethmoid is articulated with the frontal bone, the sphenoid, the superior maxillary bones, the nasal, the lacrymal, the palate bones, the inferior turbinated bones, and the vomer, at the parts already indicated.

In structure the component plates are compact, unless at the *crista galli*, which contains some cancellated tissue, and the middle and superior turbinated bones, which seem less dense than the horizontal plate.

The ethmoid bone consists in the fœtus of loose, soft, brown-coloured substance, contained in a thick vascular membrane, and disposed in the cubical shape, but without the complicated arrangement of convoluted plates by which it is afterwards distinguished. Into this the nervous fibrils penetrate, and are observed to be ramified. This continues at least four or five months after birth, when these fibrils become surrounded with compact bone deposited in their interstices, and in this manner the perforated plate is formed by deposition round the nerves. About the same time, on the mesial plane is observed a vertical plate, which gradually becomes condensed into solid bone, in the shape of the *crista galli* and middle partition. Soon after, as the bone increases in size, excavations are formed, and the soft uniform substance is removed, while plates of thin but solid bone interposed between thick vascular membranes are observed to be formed. The plates, which are slightly convoluted, become thinner and more solid, and are at length moulded into the superior and middle turbinated bones. The ethmoid is generally complete about eighteen months after birth; and about the second year its different component parts may be recognised. The holes of the perforated plate are, however, larger and more numerous at this age than afterwards. The minute grooves (*canaliculi*,) described by Scarpa, in the lateral portions, are also more distinct and larger than subsequently. It ossifies therefore in four points

Special Anatomy.

one for the horizontal plate, one for the vertical, and one for each lateral mass.

The sphenoid bone.

The sphenoid, wedge-like or cuneiform bone (*os cuneiforme, os sphenoides*, Σφηνοειδὲς)—a symmetrical bone, of a very irregular and complicated shape, wedged as it were between the bones of the scull, may be distinguished into cerebral or superior, and anterior-inferior or external surfaces. By the ancient anatomists it was compared to a bat with the wings expanded, and is by them distinguished into a body and wings, great and small. (Fig. 4.)

The cerebral surface, covered by the dura mater, is superior, and forms part of the internal base of the scull. It may be distinguished into four parts; the middle, the upper anterior, and two lateral. The middle consists of a smooth surface, on which lie the olfacient or first pair; a transverse groove for the commissure of the optic nerves; a transverse eminence named the olivary (*processus olivaris*); a deep quadrilateral pit in which is contained the pituitary gland, named the Turkish saddle (*sella Turcica, ephippium, fossa pituitaria*), with a slight groove on each side for the transit of the sixth pair of nerves, and bounded behind by an elevated eminence, with two processes, named the posterior clinoid or couch-like processes. The sides of the *sella Turcica*, especially before and behind, present generally a pit, in which is lodged part of the carotid artery. The anterior serrated margin of this surface is articulated with the ethmoid bone; the posterior with the cuneiform process of the occipital bone.

The upper anterior portions consist of two triangular spaces, united to the middle by their base. This surface, which corresponds to the anterior lobes, is bounded before by a serrated margin articulated with the frontal bone, behind by a smooth curved margin, which corresponds to the Sylvian fissure, and marks the separation of the anterior and posterior cerebral lobes. This arch, which may be named the *sphenoidal*, terminates before in a sharp process, named the ensiform, articulated with the frontal bone, and behind in a similar though smooth process named the anterior clinoid. Anterior to this, and between it and the olivary process, is the optic hole (*foramen opticum*), for the transmission of the optic nerves on each side. Behind this hole, and on each side of the olivary process, is the groove in which the internal carotid is lodged. The triangular surfaces now described are commonly named the small wings (*alæ minores sive superiores*), or the wings of Ingrassias. (Fig. 4, a, a.)

The lateral surfaces are concave, marked with cerebral depressions and vascular grooves, four-sided, low behind, but rising to an angular peak before, and are commonly named the large wings (*alæ majores, alæ mediæ*, Soemm.) (A, A.) From the small wing of Ingrassias it is separated by a longitudinal fissure, extending obliquely from the sides of the *sella Turcica* upwards and laterally. Through this opening, which is large below and narrow above, and is variously named the superior orbitar fissure, the sphenoidal fissure (*foramen lacerum superius et anterius*, l, l), pass the third pair or oculo-muscular nerves, the fourth or pathetic, the first or ophthalmic branch of the fifth, and the sixth or abductor nerves, the optic vein, and a branch of the lacrymal artery. Behind, and a little to the outside of the sphenoidal fissure, is the round or superior maxillary hole (*foramen rotundum*, r, r), for the transmission of the second or superior maxillary branch of the fifth pair; and still more posterior and laterally the elliptical hole (*foramen ovale*), for the transmission of the third or inferior maxillary branch of the fifth pair. This part of the large wing terminates behind in an angular process named the *spinous*, articulated with the petrous portion of the temporal bone, and in which is seen the spinous hole (*foramen spinosum*), through which a branch of the external carotid, the middle meningeal artery (*arteria duræ matris media, maxima*), enters the cranium to be distributed on the *dura mater*.

The lateral surfaces terminate before in an elevated recurved peak, surmounted by a triangular surface mostly serrated, but smooth behind, articulated with a similar surface of the frontal bone; laterally in a concave serrated margin articulated with the convex serrated margin of the temporal bone; and behind in a smooth margin, which, with a similar one of the pyramidal portion of the temporal bone, forms the anterior fissure of the base of the cranium (*foramen lacerum anterius in basi cranii.*)

The anterior inferior surface presents several distinct regions. On the mesial plane, at right angles to the serrated margin, is a vertical crest or spine, which terminates below in a process denominated therefore the *azygos* or *rostrum*. (*a.*) The upper crest is articulated with the vertical plate of the ethmoid bone, the lower with the fissure of the *vomer*. On each side the bone is convex, from the swelling of the sphenoidal sinuses, into which may be seen a small opening, which, however, is nearly closed by an osseous plate, variable in shape, named by Bertin the sphenoidal turbinated bone. The interior of the sinuses is parted into two halves by a middle plate, corresponding to the external crest. On each side of this middle portion is the outer surface of the small wings, forming part of the orbit penetrated by the optic hole, to the circumference of which are attached the *levator palpebræ superioris* and *levator oculi* above, the *depressor oculi* below, the *adductor* within, the *abductor* without, and the superior oblique (*trochlearis*) between the two last. Between the margins of the small and great wings is the outer orifice of the sphenoidal fissure; and on the other side of this is the orbitar surface, hollow, bounded above by the serrated margin of the triangular area, without by that of the malar process, and below by a smooth ridge, which, with the posterior one of the superior maxillary bone, forms the spheno-maxillary fissure. Immediately between this is the external orifice of the superior maxillary hole. External to the malar serrated edge is the zygomato-temporal surface, hollow, inclosed within three curvilinear serrated margins and two rounded ones, and parted into two portions, the temporal and zygomatic, by an elevated ridge, to which are attached aponeurotic slips of the temporal muscle. Below this transverse crest is a concave surface, lost in the external pterygoid process, and forming part of the zygomatic fossa, terminating, like the similar part of the large wing, in the spinous process, and presenting first the elliptical, and then the spinous hole.

The rest of the outer surface of the sphenoid bone terminates in two prominent bony plates, the one external, thin, and flat, the other internal, thicker, and more pointed, named the pterygoid or wing-like. These processes rise almost at right angles to the plane of the posterior part of the lateral wings by a thick prismatic piece of bone, common at first to both. Soon, however, they become distinct, especially behind. The external plate, which is thin, broad, and sharp, rises from the lateral portion between the round and oval hole, and, with its plane turned obliquely outwards, terminates in an end round below and before, sharp behind. (b, b.) To the outside of this plate, which is irregularly rough, with part of the zygomatic fossa, is attached the external pterygoid muscle. The inside of the external plate is concave, and forms, with the internal, part of the pterygoid *fossa*, in which are lodged the internal pterygoid muscle and the external *peristaphylinus*. The internal pterygoid process, rising on the inside, narrower and more curved, terminates in a bent point named the unciform or hook-like process (c, c), over which in a

Special Anatomy.

The sphenoid bone.

peculiar groove moves the tendon of the external *peristaphylinus*. The base of the external process generally presents a longitudinal superficial depression named the navicular. Between the external and internal is left a triangular space, which is completed by the pyramidal portion of the palate bone. The base of the internal pterygoid process is penetrated by the Vidian canal (*canalis Vidianus*), larger before than behind, through which is reflected the posterior twig of the spheno-palatine ganglion, sometimes named the Vidian nerve (Plate X. fig. 2), to join the sixth at its connection with the great sympathetic, with some blood-vessels.

The posterior part of the body of the sphenoid bone presents a quadrilateral surface of some extent, rough, cartilaginous, and sometimes excavated into small cells, for articulations with the cuneiform or basilar process of the occipital bone. In the young subject this surface is soft and cartilaginous; but as age advances it becomes more solid, and is at length inseparably ossified with the occipital bone. From this circumstance Soemmering describes the sphenoid and occipital as one bone, under the name of spheno-occipital; a method in which he has been followed by Meckel. The bone, however, is so complicated in shape and the arrangement of its parts, that it is perhaps more intelligible to describe it separately.

The sphenoid bone is articulated with all the bones of the scull at the points already indicated, and with the following bones of the face—the malar, the palate bones, and the vomer, sometimes with the superior maxillary.

It consists, when fully formed, chiefly of compact bone; for the plates even of its cells, though thin, are compact and firm bone, and its general density is considerable.

In the fœtus the sphenoid bone, after remaining cartilaginous till the third month, begins to ossify in the lateral portion, near the roots of the pterygoid processes. Two other points of ossification appear on the large wings, and, coalescing with those already formed, constitute a single mass on each side for each lateral portion. About the same time the body in the sella Turcica begins to be formed; and shortly after the small wings are formed separately, and coalesce, first with each other, and then with the body. In the fifth month the bone has the same figure which it retains through life, but the extremities of the wings are soft and cartilaginous; the body of the bone is uniform, loose, bony matter; the holes are large and imperfect; the optic hole is triangular; the inferior maxillary hole and the spinous are incomplete behind—sometimes the latter is not formed; and the Vidian canal is a mere fissure between the base of the external and internal pterygoid processes. The bone at this time consists of five portions, one for each small wing, one for each large wing, and one for the body of the bone. At the period of birth, though these parts are still separable, in general the small wings become united with the body, and the bone thus consists of three pieces. Eventually, by the union of the two large wings with the sides of the body, the bone is consolidated into one portion, the optic foramen is rounded, the oval hole completed, and the Vidian fissure is at the same time converted into a canal. In this state the sphenoid continues for several years, growing in every direction, and diminishing the size of its several apertures; till, about the age of puberty, the body becomes excavated into two lateral cavities with compact walls, separated by middle partitions. These are the sphenoidal sinuses, the formation of which is generally simultaneous with the completion of the bone in all its parts.

The occipital bone.

The occipital bone (*os occipitis, os proræ*), symmetrical, of a rhomboidal or trapezoidal shape, placed on the median line, occupying the posterior inferior region of the scull, may be distinguished into three parts, the occipital bone proper, the condyloid processes, and its cuneiform or basilar process. It presents two surfaces, an external or occipital, and an internal or cerebral.

The external surface is convex and smooth above the middle, where it is covered by pericranium and the tendinous fascia of the occipito-frontal muscle. Nearly in the middle the bone is elevated into an irregularly triangular eminence named the occipital protuberance (*tuber occipitis*), the size and shape of which vary according to the energy of the muscles connected with the strong fibrous fascia named the cervical ligament. When most strongly marked, the apex of the protuberance to which the *trapezius*, by means of the ligament now mentioned, is fixed, is prominent downwards, and occasionally incurvated or unciform. From this prominence a line may be traced, obscurely at first, distinctly below, descending to the great aperture (*foramen magnum*), for the transmission of the spinal chord. To this ridge or crest (*crista occipitis*), which is not always exactly in the middle, a fibrous fascia of great strength is attached, from the protuberance to the aperture, giving support and attachment to the muscles on each side, and named the posterior cervical ligament (*ligamentum cervicis, ligamentum nuchæ*). On each side of this ridge the surface is marked by various irregularities, the effect of muscular impressions.

A semicircular ridge, extending from the protuberance on each side to the margins, where it joins a similar ridge on the temporal bone, and named the *superior semicircular*, gives attachment above to the occipital part of the *epicranius*, the lateral parts of the *trapezius* below, and at its marginal end to that of the sterno-mastoid. When the crest begins to be distinct, a similar ridge proceeds in a semicircular direction to the margins of the bone, where it becomes more elevated, and occasionally changes its direction by a slight bend downwards and forwards. To the space between these two lines, which is rough and irregular, the *complexus*, and part of the *rectus capitis posticus major*, are attached within, and the *splenius capitis* without; while the *rectus capitis posticus major* and *minor*, and the *obliquus capitis superior*, are inserted by a strong fascia into the superior semicircular line. (Plate XXIV. fig. 6.)

The lower region of the bone presents the vertebral aperture, generally oval, with the large diameter antero-posterior, sometimes circular, occasionally rhomboidal or lozenge-shaped. At its anterior half are the condyloid processes, tipped with cartilage and synovial membrane, elliptical in shape, converging forwards, and parted by a sinuosity in the posterior part of the cuneiform process. By this opening the spinal chord with its membranes, and the spinal nerves, pass outwards, and the vertebral arteries enter the cranium. The posterior extremity of the condyloid processes is bounded by a depression, containing generally a small hole, sometimes two, for the transit of vessels not constant; externally is a rough surface, for the attachment of the *rectus capitis lateralis*; and above is the anterior condyloid hole, for the transmission of the twelfth cerebral or hypoglossal nerve.

The portion of bone anterior to the great aperture is the cuneiform process, the outer surface of which is depressed behind for the insertion of the *recti capitis interni majores* and *minores*; but smooth before, where it is covered by the mucous membrane of the pharynx.

The internal or cerebral surface, which is concave, is divided more or less regularly into four compartments, in the following manner. From the apex descends a groove nearly in the median line, though generally inclining a little to the right, to near the middle between the apex

Special Anatomy.

The occipital bone.

and upper margin of the great aperture, where it makes a rectangular turn to the right, leaving in the middle an elevated eminence, on the other side of which a similar groove, though always smaller, proceeds to the opposite margin of the bone, while from the same point descends an elevated ridge, more or less acuminated, to within half an inch of the great aperture. This arrangement produces in the inner surface of the occipital bone a cruciform appearance, which is occasionally named the *spina cruciata*, while the compartments are distinguished as superior and inferior right and left occipital *fossæ*. The rectangular groove, which is the continuation of the sagittal, formed in the inner surface of the parietal bones, contains first the lower part of the superior longitudinal sinus, then the lateral sinus, the plates of the *dura mater* being fixed to the lateral ridges on each side. The groove on the left side contains the left lateral sinus; and to the central tubercle and ridge the *falx* of the *cerebellum* is attached. In the two upper compartments, which are much marked by cerebral eminences and depressions, the posterior cerebral lobes are lodged, while the cerebellic lobes are contained in the inferior compartments. (Fig. 7.)

On each side of the large aperture is seen a short segment of a broad circular furrow, which terminates on the margin of the bone in a smooth sinuous depression. The first part is the termination of the lateral groove, containing the end of the lateral sinus; the second, the sigmoid notch, forms, with a similar one on the temporal bone, the jugular hole (*foramen lacerum posterius in basi cranii, foramen jugulare, incisura jugularis*), for the commencement of the jugular vein, the glosso-pharyngeal nerve, the *nervus vagus*, and the accessory nerve. Occasionally there is a proper notch for the *nervus vagus* in the anterior part, and occasionally one for the glosso-pharyngeal.

Anterior to the large aperture is the inner surface of the cuneiform process, concave transversely for lodging the *medulla oblongata* before it quits the cavity of the cranium (*fossa basilaris*), marked by a groove at the sides for the inferior petrous sinuses, and terminating abruptly in a broad quadrilateral surface incrusted with cartilage, for articulation with the posterior part of the sphenoid bone.

The margins of the occipital bone posterior to the inferior lateral groove are serrated for articulation by suture with the parietal and temporal bones. The upper margins form a salient angle, nearly rectangular, for articulation with the re-entrant angle formed by the two parietal bones. The sides of this angle, however, vary in direction from the presence or absence of Wormian bones (*ossa Wormiana, triquetra*). Another salient angle, but always obtuse, is formed opposite the superior lateral grooves, for articulation with the re-entrant angle formed by the parietal and temporal bones of each side. A third angle is formed by the jugular eminence, an elevated process placed between the inferior lateral groove and the jugular notch, and which is tipped with cartilage for articulation with a corresponding surface of the pyramidal portion of the temporal bone. Anterior to the jugular notch the margin of the bone is smooth, but articulates by fibro-cartilage with the posterior surface of the temporal pyramid, leaving a small space unarticulated between the anterior extremities of both bones, which form a common aperture.

The occipital bone is thick along the crucial spine, the tubercles, and at the condyloid process; but thin in the centre of the four occipital fossæ, at which the external and internal tables are united with little or no *diploe*, and are not unfrequently translucent. The cuneiform process is cancellated.

In the fœtus it consists of four pieces, one for the occipital bone proper, one for each condyloid portion, and one for the basilar process. The ossification of the occipital portion commences near its middle, corresponding to a point above the occipital protuberance, and extends by radiating fibres all round to the margins of the bone. At this time the occipital portion has the shape of a *cardium;* and the apex not being formed, a space is left through which the brain is felt pulsating, named the posterior fontanelle. About the same time ossification appears in two quadrilateral portions on each side of the large aperture, and in an oblong parallelogram anterior to it. Though these enlarge and approach each other, at the period of birth the apex is still incomplete, and the posterior fontanelle is open; and even at the inferior angles of the occipital portion, where it joins the condyloid portions, a space of the same kind is left on each side. After birth, as ossification advances rapidly, the apex of the occipital portion is gradually enlarged, the Wormian bones on each side are formed, and the condyloid and basilar portions uniting with the occipital, the bone is consolidated about the third or fourth year. The traces of the lines of union may sometimes be recognised so late as the seventh year.

The occipital bone is articulated immovably by its margins with the sphenoid bone, the two parietal, and the two temporal bones; movably by its condyles with the atlas.

It is also connected with the second vertebra by means of a ligament, which passes from the odontoid process to the inner margins of the condyloid processes.

The parietal bones.

The parietal bones (*ossa verticis, ossa bregmatis, ossa parietalia*), two bones united with each other on the mesial line, are quadrilateral, quadrangular, convex externally, concave internally, occupying the upper, middle, and lateral parts of the cranium. (Plate XXVI. fig. 4 and 5.)

The external convex surface, which is covered by the *epicranius* above and temporal muscle below, presents above and behind a hole for an artery and vein, variable however in position and existence; in the middle the parietal eminence, prominent in youth, indistinct in advanced age; and somewhere between its middle and lower margin a curvilinear ridge, the continuation of that on the frontal bone, and terminating near the lower angle of the parietal for the attachment of the temporal fascia, below which the bone is covered by the temporal muscle.

The internal concave surface, lined by the *dura mater*, is marked by digital eminences and depressions corresponding to those of the cerebral convolutions. The superior edge is marked by a half-groove, which, with that of the opposite bone, constitutes the sagittal for lodging the superior longitudinal sinus; within this, depressions more or less deep, corresponding to the granules of Pacchioni; towards the centre the parietal pit, corresponding to the eminence of the external surface; and ascending from the inferior anterior angle arborescent grooves, in which the large meningeal artery is lodged. (m, m.) Parts of these grooves are occasionally converted into canals by the growth of bone over their margins.

The parietal bone is bounded by four margins. By the superior, which is serrated, it unites on the mesial plane with the opposite bone, forming the *sagittal suture;* by the anterior or coronal, also serrated, it is articulated firmly with the frontal bone, forming the *coronal suture;* and the posterior, also serrated, forms with the posterior margin of the corresponding bone a re-entrant angle, in which the occipital, occasionally with Wormian bones, is articulated. The lower margin alone, which is a concave curvature, is obliquely acuminated before, acuminated and serrated in the middle for imbrication with the temporal

Special Anatomy.

bone, and serrated behind for articulation with the upper margin of the mastoid process.

The parietal bones.

These margins form by union four angles, an anterior and posterior superior, and an anterior and posterior inferior, of which the most important is the anterior inferior, by reason of its presenting the origin of the meningeal groove on its internal surface. The parietal bone, consisting of an external and internal table, with interposed *diploe*, is thin, especially below its middle; and the *diploe* is small, and in some points obliterated. It is ossified from one point, commencing at the protuberance, and radiating all round to the margins. Previous, and some time subsequent to birth, its mesial margin and anterior and superior angle are not formed; and the brain is here covered by *dura mater*, *pericranium*, and integuments only, forming, as already mentioned, the *bregma*, or anterior fontanelle. By the completion of the bones, however, the margins and angles meet, and the fontanelle is closed. This is generally effected in the course of the second year.

The temporal bones.

The temporal bones (*ossa temporum*), rather irregular in shape, are placed on each side at the lateral and inferior parts of the cranium.

Each bone presents an external or auricular surface, an internal or cerebral, and a circumference.

The external or auricular surface presents, above and before, a large convex surface, part of the temporal fossa lodging part of the temporal muscle; before, the zygomatic process, long, pointed, and terminating in a serrated extremity, where it is united with the malar bone to form the *zygoma* (fig. 2, z), to the upper surface of which the temporal fascia is attached, to the lower the masseter muscle; behind, a flat surface of an irregularly rounded shape, terminating before in the mastoid process (*processus mammillaris, mastoideus*, m), and behind in a serrated margin, which unites with the occipital bone. Between the mastoid process and the serrated margin behind is a rough surface for the *splenius*, small *complexus*, and sterno-mastoid; and below is a pit, in which the origin of the digastric muscle (*biventer maxillæ*) is lodged.

The zygomatic process is connected to the temporal bone by two roots, one of which, anterior, inferior, and transverse (*processus transversus*), forms the anterior brim of the glenoid or articular cavity, in which the condyle of the inferior jaw is lodged; the other, superior and posterior, forms first the external and then the posterior brim of the same cavity. Behind this posterior brim is an irregular fissure termed the glenoid (*fissura Glasseri*), which indicates the original line of separation between the superior or squamous and the inferior or pyramidal portion of the bone, and through which pass the tendon of the anterior muscle of the *malleus*, some vessels, and a nervous twig named *chorda tympani*.

In the angle between the mastoid and zygomatic process is an elliptical opening from five to six lines in diameter, leading into a cylindrical cavity, the direction of which is obliquely forwards. This orifice, which is the external ear-hole (*meatus externus*, o), leads into the tympanal cavity, from which it is separated, in the recent subject, by a thin membrane only (*membrana tympani*). The three lower thirds of this orifice are formed by a distinct bony ring, which is rough, and perforated by holes for the insertion of the cartilages of the external ear. On the outside of the lower part of this bony ring is a strong process, varying from half an inch to 12 lines in length, nearly round, but terminating in a sharp point, and therefore, from its resemblance to the style of the ancients, named the *styloid process*. (σ.) Behind its base, and between it and the mastoid process, is a small hole, the stylo-mastoid, for the exit of the facial nerve. (Plate XXVI. fig. 2.)

Special Anatomy.

The temporal bones.

The inner or cerebral surface, marked by cerebral impressions and arterial furrows, is distinguished particularly by a pyramidal eminence of bone rising obliquely from it, and a deep sinuous groove, making part of the lateral, in which is lodged part of the lateral sinus.

The pyramidal portion (*pyramis*, fig. 3, p), named also the petrous (*pars petrosa*), from its hardness in several of the lower animals, may be distinguished as a truncated pyramid, bounded by four planes, one of which, the external, has been already described. Of the other three, one superior, marked by cerebral impressions, presents a semilunar depression for the Gasserian or trigeminal ganglion, the upper orifice of the carotic canal, a slight furrow, the extremity of the opening through which a branch of the Vidian nerve passes, and an eminence which indicates the situation of the superior semicircular canal. Another posterior, separated from the last by a sharp margin, traversed anteriorly by the groove of the superior petrous sinus, presents, first, an eminence indicating the posterior semicircular canal; and, secondly, an orifice, the internal auditory hole (*meatus internus*), parted by a septum into an upper orifice communicating with the Fallopian aqueduct for the facial nerve, and a lower pit containing minute holes communicating with the labyrinth, and transmitting the filaments of the eighth or auditory nerve.

The lower or third plane surface of the pyramidal process, which is external and connected with the occipital bone, presents, first, at the lower end of the external depression a cartilaginous, rough surface, where it adheres to that bone; then a large sinuous cavity, the jugular notch, forming, with that on the occipital bone, the hole for the exit of the jugular vein, often separated by a bony process into two, the first of which is for the *nervus vagus*, the second for the jugular vein; a sharp ridge (*processus vaginalis*) at the base of the styloid process, separating the jugular notch from the glenoid cavity; a circular hole, the external orifice of the carotic canal (*canalis caroticus*), for the entrance of the internal carotid and the exit of the sixth nerve; a small hole terminating the aqueduct of the *cochlea*; and, lastly, a rough surface for the attachment of the internal *peristaphylinus*, and the external muscle of the *malleus*. At the line of junction between this plane and the posterior is generally seen part of the groove for the inferior petrous sinus. (Plate XXVI. fig. 3.)

The circumference is united behind by a serrated margin with the occipital bone; above by a margin, partly serrated, partly imbricated, with the parietal bone and posterior part of the large wing of the sphenoid; and before and below by a serrated margin with the lower part of the same wing. This part, named generally the squamous, forms with the pyramid a re-entrant angle, in which is received the spinous process of the sphenoid bone; and close beside which is the orifice of the Eustachian tube (*iter a palato ad aurem*), the canal which leads from the throat to the tympanal cavity. The truncated extremity of the pyramid, which is received by the re-entrant angle formed by the sphenoid and occipital bones, presents the upper opening of the carotic canal, which is imperfect above, and in the recent body is completed by the *dura mater*.

The temporal bone is thin before and above, where it consists of two tables with intermediate *diploe*. The mastoid process in the adult consists of numerous communicating cells, lined by very delicate periosteal mucous membrane, continued from the tympanal cavity, with which they communicate. The pyramidal portion is compact and hard, and contains with other parts the labyrinth or internal ear.

Nothing is more interesting than the developement of

Special Anatomy.

The temporal bones.

the temporal bone. It is ossified in three portions,—the large, flat, or squamous; the tympanal ring; the pyramidal, with the mastoid, and the styloid process.

At an early period the pyramidal portion is perfectly formed round the several soft parts, and though porous and spongy, dense bone is seen in the site of the semicircular canals. The different orifices are large and distinct. The tympanal cavity, however, is quite incomplete; and though the carotic canal is formed, the Eustachian tube is in the shape of a mere groove. The size of the pyramid is greater than subsequently in proportion; and the part behind the open tympanal cavity, which is bulky, is to constitute the mastoid process, which however is still a shapeless mass. The squamous portion is thin and almost scaly at birth, with the zygomatic process well marked, and a ring of bone, incomplete at the upper margin, attached to its inferior and posterior part. By this, which afterwards constitutes the ring of the external ear-hole, it is fixed to the pyramidal portion in such manner that the part behind the ring is rather larger and longer than the part before; and the pyramid, instead of projecting, as afterwards, is short and thick. At this period also the flat portion uniting with the occipital bone is not formed, and there is therefore an opening or fontanelle at this point of the cranium. Soon, however, the squamous becomes united with the pyramidal portion; the tympanal ring is fixed to both; the Eustachian tube is completed; and, at the posterior end of the pyramid, bone is deposited and extended in a tabular layer of some thickness. The mastoid process, however, cannot be recognised; and it is only some years after birth (about seven) that a small oblong elevation begins to be visible behind the posterior limb of the auditory ring. If at this time the process is divided, cells of the kind afterwards seen in this part are not distinct; but as its enlargement proceeds, cells begin to be formed about the same time, and at the same rate, as the frontal, ethmoidal, and sphenoidal cells are formed. The figure of the bone also is altered, in consequence of the change which the component parts undergo in relation to each other. The squamous portion expands, the anterior part of the pyramidal portion is elongated and tapers, the posterior and the mastoid parts enlarge, and at a later period the styloid process begins to appear amidst the muscles attached to it.

The temporal bone is united immovably with the sphenoid, parietal, occipital, and malar bones; and the inferior maxillary is connected to it by articulation. In the tympanal cavity, also, are contained the four tympanal bones, to be considered afterwards.

Wormian bones.

Besides these uniform bones of the cranium, there are occasionally found one or more supernumerary bones, which vary much in number, size, and situation. Most usually they are found in the line between the occipital and parietal bones, causing the lambdoidal suture to vary much in regularity; and occasionally, instead of the apex of the occipital bone, is found a single supernumerary bone. They are observed less frequently at the inferior anterior angle of these bones, and at the temporo-parietal sutures, and still more rarely at the base of the cranium. These bones, to which attention was originally drawn by Wormius, by whose name they are still distinguished (*ossa Wormiana*), may be regarded as effects of the aberration of the ossific process. Though they have been also named triangular (*ossa triquetra*), their shape is extremely variable. They are similar in structure and mode of union to the parietal and occipital bones; and though they are not entitled to the epithet of cranial keys (*claves cranii*), often given them, they may be viewed as appendages to the cranial bones, which are then to be regarded as incomplete. The most important fact in their history is, that they are most frequent in young subjects, and in those in whom ossification is imperfect. As they are rarely found in advanced age, it may be inferred that they eventually become consolidated with one or other of the bones to which they adhere.

§ 5. *The Face.* (*Ossa Faciei.*)

The face.

The face, situate before and below the cranium, is bounded above by that cavity, on the sides by the zygomatic arches, and behind by a space corresponding to the upper region of the pharynx. Symmetrical in disposition, its anterior surface is trapezoidal, the largest side being above, its vertical section triangular, and each side irregular. The bones of which it consists are those of the upper jaw, comprehending thirteen separate pieces, two superior maxillary bones, two malar bones, two nasal bones, two lacrymal bones, two inferior turbinated bones, two palate bones, and one vomer; and the single lower jaw. (Plate XXVI. fig. 8.)

The upper jaw-bone.

The superior maxillary bone (*os malæ, maxilla superior*) is the basis of those of the upper jaw, and forms a centre, with which the others are connected. Though in shape irregular, it may be distinguished into zygomato-facial, orbitar, and naso-palatine surfaces. (Fig. 6.)

The zygomato-facial surface, irregularly convex and concave, consists of two divisions, the facial and zygomatic. The first presents the nasal or ascending process, terminating above in a serrated margin, articulated with the frontal bone; behind in a groove concurring with a similar one in the lacrymal bone to form the lacrymal canal; before by a similar margin joining with the nasal bone; and below, a pit for the insertion of the levator of the upper lip and nose (*levator labii superioris alæque nasi*). The facial surface below this, bounded on the mesial side by a sinuous hollow, the nasal, and a spine forming with that of the opposite side the nasal spine, presents above, the superior maxillary hole for the exit of the second branch of the trigeminal nerve, the canine *fossa* for lodging the *levator anguli oris*, separated by an elevation from the incisive *fossa* for lodging the myrtiform muscle (*depressor alæ nasi*). The facial region is separated from the zygomatic by a rounded margin, the upper extremity of which is rough and hollowed for articulation with the malar bone (*os genæ, os jugale*); while the posterior forms part of the temporal *fossa* before, and a distinct protuberance behind corresponding to the posterior part of a large cavity denominated the maxillary (*antrum maxillare, sinus maxillaris*). This cavity, indeed, corresponds also to the canine fossa and the external protuberance.

The orbitar surface, which is flat, and slightly oblique in direction, forming the inner half of the lower wall of the orbit, is bounded within by a sharp line for articulation with the ethmoid bone, without by the rough malar surface, and traversed through its posterior half by a groove for the maxillary vessels and nerve, terminating partly in the sinus, partly in the superior maxillary hole. The posterior margin of this surface, which is obtusely rounded, forms with the sphenoid bone the spheno-maxillary fissure; and its internal or mesial angle is articulated with the ascending process of the palate bone.

The naso-palatine or mesial surface of the bone is complicated. Before and above is seen the inner surface of the nasal or ascending process, traversed by vascular and nervous grooves, and covered by the pituitary membrane. Behind this is the lacrymal groove, terminating in the nasal, which is converted into a canal by the inferior turbinated bone, below which it opens; and the open-

Special Anatomy.

The superior maxillary bone.

ing into the maxillary sinus, large in the detached bone, but contracted below by the inferior turbinated, and behind by the palate-bone. This sinus, which is of an irregular tetrahedral shape, corresponds before to the canine *fossa*, behind to the zygomatic tuberosity, above to the orbitar plate, and below to the alveolar arch. Below this is the palatine plate (*apophysis palatina*), quadrilateral and horizontal, concave and smooth above, where it forms the lower wall of the nostrils, concave and marked by vascular orifices below, where it forms the anterior part of the hard palate. (Fig. 7.) The anterior part of the process is elevated into the nasal spine; its mesial margin, which is thick and marked by numerous grooves, one unusually large for the naso-palatine nerves and vessels (*canalis incisivus vel Stenonianus*), is joined to that of the opposite side, forming a groove in which the lower margin of the vomer is received; and the posterior, which is thin, is attached to the square plate of the palate-bone, which thus completes the palatine vault.

The palatine is separated from the zygomato-facial region by a semiparabolic arch, perforated in the adult by eight honeycomb-like pits (*alveoli*), in which the roots of the teeth are implanted, and therefore named the *alveolar* arch. Of these pits the first two are the smallest, the next three larger, and the last three very large,—an arrangement which renders the alveolar arch narrow before, and broad on the sides and behind.

The superior maxillary bone is united, at the points indicated, to that of the opposite side, to the frontal bone, to the ethmoid, to the nasal, to the lacrymal, to the palatine, to the malar, to the inferior turbinated bone, and to the vomer.

It is ossified in one piece. In the fœtus its divisions are completely formed, except the orbitar plate, the sinus, and the *alveoli*. In the former, the superior maxillary canal is a slit; and the latter is a mere depression on the nasal surface of the bone. This, however, becomes larger and more capacious, not by excavation, but by the extension of its walls by bony deposition. The alveolar arch in general consists of two parabolic plates united by transverse *septa*, so imperfect, that the whole intermediate groove communicates freely. These osseous plates are not uniform in number. In some maxillary bones there are four, and a fifth like a mere line at the bottom of the groove; in others six *alveoli*, viz. four temporary, and two permanent *alveoli*. These plates are formed by deposition round the dentiferous sacs.

The malar or cheek-bone.

The malar bone (*os jugale, os genæ*) is a quadrilateral bone, approaching the rhomboidal shape, but bounded by curved lines. It presents three surfaces, a facial, an orbitar, and a zygomatic; and four angles, a frontal, a temporal, a zygomatic, a superior maxillary, and an inferior maxillary. (Fig. 7 and 8, g.)

The facial surface is convex and smooth, marked by one or two holes (*foramen jugale*) for vessels and nerves, and, with the zygomatic process gives attachment below to the zygomatic muscles.

The orbitar surface, which is concave, directed obliquely upwards, projects backwards from the facial plate, and forms the outer wall of the orbit between the frontal and sphenoid bone above, and the superior maxillary below. It presents the internal malar hole, or the inner orifice of that seen in the facial surface. The posterior edge is rough and serrated for conjunction with the sphenoid bone.

The zygomatic surface is a sort of angular concave recess between the orbitar plate above and the facial before, and is chiefly important in forming the anterior part of the temporal fossa. In the angle between the orbitar and facial plates is seen a small hole, which communicates with the internal malar above, and the external malar before. The anterior part of this surface is rough, and unites with the external or malar process of the superior maxillary bone.

Special Anatomy.

The cheek-bone.

The superior or frontal angle is serrated for uniting with the external angular process of the frontal bone. The temporal is long and pointed, and rough above, where it joins the temporal bone to form the *zygoma*, to which the temporal fascia above and the masseter below are attached. The superior maxillary or orbitar is also pointed, and joins the rounded ridge at the base of the ascending process of the superior maxillary bone. The inferior maxillary is obtuse-angled, and joins the lower angle of the malar process.

Wedged between the bones of the scull and face, the malar bone is connected to the frontal, the temporal, the sphenoid, and the superior maxillary. It is ossified from a single point.

The nasal bone.

Each nasal bone (*os nasi*) is quadrilateral and trapezoidal. Of its two surfaces, the external, smooth and slightly convex, is covered by the periosteum and the pyramidal muscle (*compressor narium*) and part of the frontal (*epicranius*). The inner, rather concave and somewhat irregular, with grooves for vessels and nerves, is covered with the pituitary membrane. (Fig. 8, n.)

The upper margin of the nasal bone, which is somewhat thick, is serrated for union with the frontal bone, on the nasal spine of which it is firmly supported. By the mesial margin, which also is thick, plain, and prolonged backwards, it is joined to that of the opposite side; while its thin external margin being imbricated beneath the mesial one of the maxillary, the central pressure is thus opposed on each side. In this manner the two nasal bones, supported above by the frontal spine, are firmly wedged between the superior maxillary, much on the same principle as the key-stone is wedged between the lateral parts of the arch. (Plate XXIV. 2 and 3, n.) To the lower margin the nasal cartilages are attached. Each nasal bone is formed from a single centre of ossification.

The lacrymal bone.

Each lacrymal bone (*os lacrymale, os unguis*) is about the size of a nail, situate at the inner wall of the orbit, occupying the space between the frontal bone above, the ethmoid behind, and the superior maxillary before. Its shape is irregularly quadrilateral, and it presents two surfaces, an orbitar and nasal, and four margins.

The orbitar surface consists of two regions, one orbitar proper, flat, and smooth, situate behind, and connected with the lateral smooth bone (*os planum*) of the ethmoid, with which it completes the inner wall of the orbit; the other, which is anterior, is at right angles to this, and is moulded into a cylindrical groove, which, with that of the superior maxillary bone, constitutes the lacrymal canal, in which is lodged the membranous tube which conveys the tears and mucus from the eye to the nose. These two surfaces are parted by a sharp longitudinal crest, to which is attached the aponeurosis of the orbicular muscle of the eyelids (*orbicularis palpebrarum*).

The nasal surface is irregular, covered by the fibromucous membrane of the ethmoid cells, and of which it makes part. It presents distinctly the angle of union between the orbitar and lacrymal portion of the bone.

This bone, which is compact, is developed from a single point, and is early formed in the fœtus.

The inferior turbinated bones.

The inferior turbinated bones, which are irregular in shape, are attached to the nasal surface of the superior maxillary by an oblique line near the lower margin of the *antrum*, with the convex surfaces turned to each other.

Each turbinated bone presents a nasal surface, uneven and marked by rough lines, with intermediate cellular

Special Anatomy.

grooves; and a maxillary one, concave, and constituting part of the inferior nasal passage. Both are invested by fibro-mucous membrane continued from the pituitary.

The turbinated bones.

Each turbinated bone is bounded by two margins,—a superior, which is fixed,—an inferior, free. Of the former, the anterior part is a thin border, joining with the superior maxillary bone at the base of the ascending process, and with the lacrymal bone by an angular slip. The middle is a short spinous part, uniting with the lateral mass of the ethmoid, and diminishing the opening of the maxillary sinus; and the posterior part, which is rounded and inclining, is attached to the crest of the palate-bone. The lower margin, which is free, is slightly convoluted on itself, so as to separate the middle from the inferior nasal passage.

The inferior spongy bone, which is formed in one piece, though perforated by vascular and nervous holes, and moulded into cells at its lower convoluted margin, consists, however, chiefly of compact bone. It is covered through its whole extent by the fibro-mucous membrane of the nasal passages.

The palate bones.

Each palate-bone (*ossa palati*), attached to the posterior part of the superior maxillary bones, to which they may be regarded as appendages, consists of three parts, a base or palatine portion, a nasal ascending or vertical portion, and an orbitar part.

The base consists of a quadrangular and quadrilateral plate of bone, placed horizontally, and attached before to the posterior margin of the horizontal or palatine plate of the superior maxillary bone, and on the inner or mesial side to the corresponding margin of the opposite bone (Plate XXVI. fig. 7, p, p), with which it forms a groove, in which is lodged the posterior part of the lower margin of the vomer. The upper surface is concave, and, with that of the superior maxillary bone, completes the lower wall of the nasal passages. The lower is almost straight, but presents a slight concavity, bounded behind by a transverse crest of bone, to which the *uvula* or soft and movable palate is attached. Behind this is a surface bounded by the posterior margin, which is sinuous and lunated, and terminates within in a pointed eminence, which, with that of the opposite side, forms on the mesial plane the palatine spine. The external margin, which rises into the nasal or ascending portion, is rounded without into a sinuous depression, which forms, with the pterygoid process of the sphenoid bone, the pterygo-palatine canal, and which occasionally, at least at its lower extremity, is entirely formed in the palate-bone.

The nasal portion, which is irregular in shape, presents on the nasal surface a hollow, rising from the square plate, and forming the posterior part of the lower nasal passage; a transverse ridge (*linea aspera*) continuous with that of the superior maxillary bone, and to which the inferior turbinated bone is attached; and then another hollow, forming the posterior end of the middle nasal passage, and with the former contracting the orifice of the maxillary sinus. Immediately above this the vertical portion is parted by a notch into two unequal parts, a posterior articulated with the base of the external pterygoid process, and an anterior articulated before with the superior maxillary bone, and within presenting cells, which unite with those of the ethmoid bone. The outer part of this cellular portion is bounded by three surfaces, one external, forming part of the zygomatic *fossa;* another anterior, resting on a corresponding surface of the superior maxillary bone; a third superior, forming part of the inner wall of the orbit. The notch between the anterior and posterior divisions forms with the sphenoid bone the spheno-palatine, for transmitting the spheno-palatine twig of the superior maxillary nerve, with some veins, and the internal branch of the spheno-palatine ganglion.

The palate bones.

The posterior margin of this vertical portion is acute above, where it is simply conjoined with the base of the pterygoid processes; but below it is moulded into a thick, strong, triangular process, projecting backwards, and marked by three grooves, one in the middle, and one on each side. In the two latter the external and internal pterygoid processes are adapted; and the middle space, being prominent, and firmly wedged between the pterygoid processes, completes the pterygoid *fossa.*

Each palate-bone is connected with six bones, two of the cranium and four of the face; the ethmoid and sphenoid, the superior maxillary, the inferior turbinated bone, the palate-bone of the opposite side, and the *vomer.*

The palate-bone, so far as is hitherto observed, is formed in one portion. In the fœtus, at the seventh month, it is completely formed; but the square or horizontal part is larger in proportion than the vertical, and remains so till the face begins to alter its shape.

The vomer.

The *vomer* or plough-share bone is symmetrical, placed on the mesial plane between the sphenoid and ethmoid bones above, and the palate and superior maxillary bones below, and forming the posterior part of the nasal partition.

In shape it is irregular, though it affects the rhomboidal. It consists of two thin plates of compact bone united at an angular line below, but separated above so as to form a deep longitudinal groove, in which the cartilaginous partition before, and the vertical plate of the ethmoid behind, are inserted. At the posterior end these plates spread out into lateral wings with intermediate grooves, in which the *azygos* process of the sphenoid bone is accurately fitted. These two parts form the upper and posterior margins. The lower consists of a single thin plate, which is received into the linear groove formed by the middle crest of the palate and superior maxillary bones. The anterior part of this margin rises more directly, to fit the nasal spine of the latter bones.

The surfaces of the vomer are smooth, occasionally concave and convex in opposite directions, and, being covered by the fibro-mucous pituitary membrane, constitute the bony partition between the right and left nasal passages. The bone is formed in a single piece, and is generally completed in the seventh and eighth month.

The lower jaw.

The lower jaw-bone (*mandibula, maxilla inferior*), symmetrical, placed at the base of the face, is of a shape nearly parabolic, with an elevated branch at each extremity. It consists of two parts, a maxillary arch, and a *ramus* at each end, each of which has two surfaces, an external or facial, and an internal or oral, an alveolar or upper margin, and a mental or lower margin. (Fig. 8 and 9.)

The external surface of the parabolic or arched portion of the lower jaw presents first on the mesial plane the *symphysis* or chin (*mentum*), indicating the original separation of the bone into two parts,—a vertical line diverging into two, so as to form a triangular eminence (*tuber maxillare* of Soemmering). (Fig. 8 and 9, x.) On each side of this is a depression for the tuft or *levator* of the chin, the anterior mental hole (*foramen menti anterius,* f), or inferior maxillary for the exit of the third branch of the fifth pair, and the external maxillary line (*m*) for the insertion of the *platysma, depressor anguli oris,* and *depressor labii inferioris.* Behind this the ascending *ramus* presents a quadrilateral surface, corresponding to the masseter (r), bounded before by a sharp line terminating in the coronoid process (b, b), behind by an obtuse one, the posterior margin terminating in the condyloid or articular process (c, c), and above by the sigmoid notch (*incisura semilunaris vel sigmoidea*) between them.

Special Anatomy. The lower jaw.

The internal or oral surface of the lower jaw presents in the middle a spine or crest (*spina menti interna*), consisting in general of three eminences, the two superior of which give attachment to the *genio-glossi*, and the lower to the *genio-hyoidei*. On each side of this is a superficial hollow for the sublingual gland, and a pit for the digastric muscle; and extending outward on each side is the internal oblique line, to which the mylo-hyoideus and the superior constrictor of the pharynx are attached. Below this is a depression for the submaxillary gland; behind, at the margin of the *ramus*, the surface is rough for the insertion of the external pterygoid; between this and the top of the oblique line is the internal mental hole, or the inner orifice of the maxillary canal; and above and round the orifice the surface is rough for the insertion of the internal ligament of the lower jaw. By this orifice the inferior maxillary nerve, or third branch of the fifth pair, with its concomitant vessels, enters the canal; and after sending branches to the alveolar arch and membranes, reappears at the external mental hole.

The upper margin of the parabolic part of the bone is moulded into a series of *alveolar* or *honeycomb-like* cavities, bounded by external and internal plates, and separated by *septa* more or less complete. These cavities are in the adult 16 in number, but are sometimes imperfect, sometimes obliterated by the removal of the teeth. This margin, which, like the corresponding one of the superior jaw, is named the *alveolar arch*, is, like it, narrow anteriorly, and wide on the sides and behind. At the posterior end of each alveolar arch the external and internal oblique lines form between them a superficial depression, in which part of the *buccinator* is lodged; and then converging as they ascend, terminate in the pointed coronoid process, to which the tendon of the temporal muscle is fixed, unless at its outer surface, which is covered by the masseter. The condyloid process, separated from this by the sigmoid notch, is broad transversely, and is contracted below so as to form a neck, which is concave within for the insertion of the external pterygoid muscle.

The inferior margin, which is obtusely rounded, and forms a more pointed curve than the upper, gives attachment only to the cutaneous muscle (*platysma myoides*). The posterior margin, also obtuse, is free, but corresponds to the parotid gland, and is therefore occasionally named the parotid margin. To this the stylo-maxillary ligament is attached.

The posterior part of the bone, named the *ramus*, forms with its body an obtuse angle of about 100°, which diminishes as life advances. (Fig. 8, a, r.)

The inferior maxillary bone is connected movably with the temporal bone by its condyloid process being lodged in the glenoid cavity of the latter. In this situation it is retained by means of three ligaments, while its motions are facilitated by an interarticular fibro-cartilage.

The *external* ligament, composed of parallel fibres attached to the tubercle at the bifurcation of the zygomatic process, descends obliquely backwards, and is fixed to the outside of the neck of the condyle of the lower jaw. It is covered by skin and the parotid gland, and is lined by synovial membrane, to part of which the interarticular cartilage is attached. The *internal* ligament, attached to the spinous process of the sphenoid bone and its vicinity, proceeds obliquely downwards and forwards, between the two pterygoid muscles, expanding, to the orifice of the internal maxillary hole, round which it is attached.

The *stylo-maxillary* ligament is an aponeurotic chord, belonging rather to the *stylo-glossus* muscle, stretching between the styloid process and the tip of the angle of the lower jaw, where it is inserted between the masseter muscle without, and the internal pterygoid within.

Special Anatomy. The lower jaw.

This articulation is so constructed that it possesses two synovial membranes, or at least a double one, the parts of which are separated by the interarticular cartilage. The latter body, which is of an oval shape, convex and concave above, to fit at once the glenoid cavity and the transverse process, but concave below for the maxillary condyle, adheres externally to the external ligament, while its inner margin is free. The upper division of the synovial membrane, therefore, adhering all round to the margins of the glenoid cavity and transverse process, after covering these parts, is reflected from the external lateral ligament over the upper surface of the interarticular fibro-cartilage. A minute slip may be then traced over the free margin of this fibro-cartilage, covering its lower surface, and thence continued over the inside of the external lateral ligament, and from it over the condyle of the lower jaw. In this manner the temporo-maxillary synovial membrane is rather composed of two parts, a superior and inferior, than absolutely double.

The inferior maxillary bone is formed in two pieces; and perhaps no bone in the human body undergoes from first to last greater changes in shape and extent than it does. In the fœtus, when first formed, it consists of two slightly incurvated portions, united on the mesial plane by cartilage, with the coronoid and condyloid process, and the intermediate sigmoid notch, rising from the posterior extremity of each. The *ramus*, however, cannot be said to be formed; and it is only some time after birth that the quadrilateral surface by which it is defined can be recognised. At birth, also, the alveolar arch consists only of two thin plates of bone, with scarcely perceptible traces of *septa*; and the periosteal coverings of the dentiferous sacs are in immediate contact with each other. After birth, bone is deposited between them, so as to form the transverse partitions of the *alveoli*, which afterwards increase in size and thickness with the bone itself, which enlarges in all its dimensions chiefly by extending backwards. Coalescing by the progress of ossification on the mesial plane, it is a few weeks after birth consolidated into one bone; and after the process of primary dentition commences, it loses the angular and acquires the parabolic shape. About the age of seven, sometimes previously, the body becomes more incurvated, and the posterior extremities enlarge backwards still more rapidly. As the process of secondary dentition advances, these extremities enlarge still more rapidly; and the angle of the jaw acquires a more prominent situation by becoming more depressed. At the time at which the facial and maxillary sinuses are formed, and the superior maxillary bone extends backwards to form its tuberosity, the posterior extremity gradually rises in the form of the *ramus*, till this part a year or two after puberty is fully an inch above the plane of the alveolar arch. During adolescence and middle life this is the condition of the jaw-bone. Towards the decline, however, the teeth drop out, and the alveolar processes are absorbed; and in old age the lower jaw consists often of a single cylindrical arch of bone placed between its two *rami*, which, retaining their original breadth and height, necessarily throw the body of the bone forwards beyond the upper alveolar arch.

The lower jaw-bone consists of two plates of compact bone, with cancellated tissue interposed, and traversed by the inferior dental canal, the walls of which, like the surface of the bone, are compact. This canal is subdivided into two parts,—one inferior, which terminates in the anterior mental hole, transmitting the mental branch of the inferior maxillary nerve; the other superior, which is parted into numerous minute passages into the *cancelli* of the bone and alveolar processes. These, it must also

Special Anatomy. The lower jaw.

be observed, consist of a peculiar form of cancellated structure. Externally their bony walls are perforated by numerous minute well-defined holes, into which, in the recent state, the vessels and filaments of the alveolar periosteum penetrate. These orifices are so numerous in both maxillary bones, that a portion of alveolar process held between the eye and the light seems entirely perforated, and, if injected, becomes completely red. This character applies chiefly to the period of youth and adolescence. After this the alveolar processes become more solid, and eventually present much fewer orifices. This structure is the result of the manner in which the bony matter is deposited round the vessels and filaments of the periosteum, which may in this and similar bones be said to communicate in this manner with those of the medullary membrane.

The Teeth. (*Dentes.*)

The teeth.

The teeth, which are implanted in the alveolar cavities, though belonging properly to the digestive apparatus as organs of mastication, are nevertheless more conveniently considered in this place. (Plate XXVI. fig. 7, 8, and 9.)

In every tooth are recognised three parts,—the crown (*corona*), the neck or collar (*collum*), and the root (*radix*). The first is the portion which appears above the gum and alveolar process, and consists of a layer of enamel, thick above and round the top, but gradually extenuated below, inclosing a small portion of compact bone. The crown may be distinguished into the crown proper, or the *summit* or *apex* of the tooth, and the *fillet* or annular portion of enamel (*annulus*) by which the sides are surrounded. The root, which consists of compact bone, is the part which is implanted in the alveolar cavity, and the outer surface of which adheres to the inner or dental surface of the alveolar periosteum, and above that to the soft part of the gum. The neck is the narrow ring where the enamel ceases and the bone begins, and to which the gum adheres all round. This part, in short, belongs neither to the crown nor to the root, and perhaps is not justly entitled to any separate consideration, unless as the portion to which the gum adheres. The crown and root, on the contrary, are important, as furnishing the characters by which the teeth are distinguished into classes.

The incisor teeth.

These are three,—the incisor or cutting teeth (*dentes tomici, incisores, primores, risorii, acuti, adversi*); the canine or tearing teeth (*dentes canini, laniarii, cuspidati*); and the molar or grinding teeth (*dentes molares*).

The incisors are in number eight, four in each jaw, and two on each side of the mesial plane. All of them agree in having the crown or *apex* wedge-shaped, or like a carpenter's adze, convex before, and slightly concave behind, with the cutting edge crenated or notched. From the edge, also, which is broad, the fillet, which is quadrilateral, contracts much to the neck, and the root is bevelled in the opposite direction to that of the crown, so as to form a quadrilateral prism, and slightly acuminated. It is always simple and elongated. Its extremity presents an orifice communicating with the interior of the tooth, and admitting the vessels by which it is nourished. The crown is separated from the root by a narrow line, varying in position in the different kinds of incisors.

The incisors of the upper jaw are broader, thicker, longer, and in general more powerful, than those of the lower, and their axes are directed downwards and forwards so as to overlap in the motions of the lower jaw those of the inferior row, and leave a triangular interval with the base upwards. Their cutting edge also is oblique, so that its mesial angle is longer than its external; and their roots are larger and rounder. The central or middle incisors are larger, broader, and stronger, than the lateral ones.

The canine teeth.

The incisors of the lower jaw are smaller than those of the upper, and their axes are directed upwards and backwards, so that they are within the superior incisors. The central incisors also are larger than the lateral ones.

The canine or pointed teeth (*dentes cuspidati*) are four in number, one in each half of each alveolar arch, immediately next to the lateral incisors. These teeth are distinguished by prominent, thick crowns, with rounded convex fillets and pointed apices. The root also, which, like that of the incisors, is simple, is larger and thicker than in the latter. The upper canine teeth, which occasionally are named eye-teeth (*ocularii dentes*), are the longest and most prominent of all. During the elevation of the lower jaw, each inferior canine tooth is interior to the superior one, and is interposed between it and the lateral incisor.

Of the molar or grinders there are 20 altogether, being five in each half of each alveolar arch. They are subdivided into two orders, small molar or bicuspid teeth (*dentes bicuspidati*), and large molar or multicuspid teeth (*dentes multicuspidati*).

The molar or grinding teeth.

The molar teeth agree in having large, broad crowns, with tubercular summits, and roots, which, though occasionally single, are much more frequently two-fold, three-fold, or four-fold. The coronal tubercles are generally parted by a deep furrow, which gradually becomes shallow as the summits wear in the progress of years. When the roots are single, which is most frequent in the bicuspid order, each lateral surface is marked by a longitudinal furrow. When two-fold or manifold, they are parted by a fissure of variable width; and sometimes they diverge considerably. The annular furrow between the crown and root is very distinct.

The axes of the upper molar teeth are directed outwards, while those of the lower order, especially the most posterior, are directed inwards. More anteriorly they are occasionally vertical.

The small molar or bicuspid teeth.

The two molar teeth next to the canine, which have smaller crowns and roots, and are less in all their dimensions than the three posterior ones, are therefore distinguished as small molars. From the circumstance of their crowns being provided with two conical *apices*, one anterior, large, and the other posterior, parted by a transverse furrow, not dissimilar to the summits of two canine teeth conjoined in one, they were denominated by John Hunter bicuspid teeth (*bicuspidati*). These teeth are smaller than the canine, especially when their roots are single. The roots, however, are often bifid, and sometimes trifid. In the first case they are bevelled on the sides, and terminate in a point. In the second and third case they are conical. The internal surface of the bicuspid teeth is very generally narrower than the external, so that a transverse section would be trapezoidal, with the narrow margin posterior.

The large molar or grinders proper.

The *third* molar tooth, or the *first* large molar, is generally very large and strong, with the crown broad and quadrilateral, surmounted by four, five, or more tubercles, and the root trifid or quadrifid and divergent in the upper tooth, more frequently bifid only and divergent in the lower. The *second* large molar tooth, though rarely so large as the first, has the same general shape; the crown rhomboidal in the upper jaw, with four apices, and the root bifid or trifid and divergent.

The *third* large molar, named also wisdom-tooth (*dens sapientiæ*), from its late appearance, is smaller than the second, generally has a narrower crown, rounded, oblong,

Special Anatomy. The teeth.

quadrilateral, or rhomboidal, with two or three apices, and a narrow root generally single and conical, often incomplete. Its axis is strongly directed inwards, especially in the upper jaw.

The dental arches. The orders of teeth now enumerated constitute arches of a parabolic or semielliptical shape, larger in general in the upper jaw than in the lower. In the upper arch especially, the curvature is more rounded or elliptical; in the lower it is more angular and parabolic,—a circumstance which, with the different directions of the axes of the incisor and molar teeth respectively, causes the upper incisors to overlap, and thereby cut upon the lower ones, while the molars are fitted to each other so as to move on mutual surfaces in the lateral motion of the jaw.

Varieties. The teeth vary in number, shape, and position.

Though the general number of the adult or permanent teeth is 16 in each jaw, or 32 in all, it may happen that, in consequence of all the wisdom-teeth not coming through the gum, there are only 28 or 30. Occasionally also the lateral incisors are wanting. In some rare instances there is a supernumerary incisor or molar tooth; and Soemmering mentions an instance in which, by the addition of four molar teeth, the total number was augmented to 36. The union of two or more teeth into one is occasionally observed.

The most usual variations in shape are observed in the incisors being excessively large and broad, in the canine being very thick and long, ascending into the *antrum*, and in some rare instances extremely small. In females the canine teeth are occasionally so small and rounded, that they have the appearance rather of rudiments than of perfect teeth. The cleft roots of the molar teeth are liable to very great varieties in shape.

The most usual variety in position is when the incisors are placed obliquely, with their margins not lateral but antero-posterior. This is in general the result of the teeth being too much crowded in a small alveolar arch; and the malposition is always greatest as the jaw is narrow, or imperfectly formed. One or two incisors even in such circumstances may be entirely behind or before the rest, so as to give the appearance of a double row. The canine teeth are liable to the same change of position; but one greatly more frequent with them is, to be placed so much before the line of the arch as to project considerably forwards, like the tusks of some animals. Another form of this variety is, when teeth appear in unusual situations, for instance the palate or pharynx, or even in the orbit.

Dentition primary. The teeth are not at all periods of life the same in number. Generally speaking, at birth, when the teeth have not appeared above the gum, the rudiments of five teeth are found in each half alveolar arch. These, which are to constitute the milk-teeth, the deciduous or temporary, appear above the gum nearly in the following order: the central incisors of the lower jaw about the end of the sixth or beginning of the seventh month; a few weeks after, the central incisors of the upper jaw; after these, the lateral incisors above or below, without determinate order; and between the 12th and 18th months the first pair of molars, either above or below. These are followed by the lower canine teeth, and about the second year by the upper canine teeth. About the end of the second year, or in the course of the third, the second pair of molar teeth cut the gum; and about the fourth or fifth year in general, the third pair of molar teeth appear. The following table of the periods at which the different classes of temporary teeth appear, given by Mr Thomas Bell, may communicate a general idea of the succession.

From 5 to 8 months,	the 4 central incisors.
From 7 to 10	the 4 lateral incisors.
From 12 to 16	the 4 anterior molars.
From 14 to 20	the 4 canine.
From 18 to 36	the 4 posterior molars.

From these periods, however, there are extensive exceptions; and in no two individuals even of the same family does the same tooth appear at the same period.

Dentition permanent. About the seventh month the milk-teeth begin to appear above the gum; and about the seventh year they begin to be shed and succeeded by the permanent set. This process begins also in the lower jaw, and advances nearly in the same order: the lower central incisors; the upper, and the lateral above and below; the first pair of molar upper and lower; the second pair of molar above and below; the canine above and below; the third pair of molar; the fourth pair of molar in the eighteenth year; and the fifth pair, or wisdom-teeth, in the eighteenth, twentieth, or thirtieth years.

The average periods of eruption in the lower jaw are given in the tabular form by Mr Thomas Bell, in the following order.

The anterior larger molars	$6\frac{1}{2}$ years.
The central incisors	7
The lateral incisors	8
The anterior bicuspids	9
The posterior bicuspids	10
The canine or cuspidati	11—12
The second large molars	12—13
The third large molars, or wisdom-teeth	17—19

Those of the upper jaw are understood to follow these at an interval of two or three months.

In structure the teeth of the human subject belong to the order of simple teeth, that is, consist of bone, invested at the crown by enamel.

The hyoid or lingual bone. The hyoid bone (*os hyoides, υ, ossa lingualia*), though entirely unconnected with the skeleton, yet as a bone to which are attached various muscles of the throat, must be noticed in this place. It is a bone, or rather a bony apparatus, consisting of five separate pieces, arranged in the parabolic form, and articulated movably with each other. These five pieces are, one middle, two lateral, and two pisiform bones.

The middle (*os medium linguæ*), named also the body, is large, broad, and square, with the anterior surface in general convex and rough, divided by a middle ridge into right and left halves, and by a horizontal line into upper and lower parts, and giving attachment on each side of the middle crest to the digastric, the stylo-hyoid, the mylo-hyoid, the genio-hyoid, and the hyoglossal muscles. The posterior surface is concave and smooth, and covered by cellular tissue, connecting it to the epiglottis. To its inferior margin, which is more extensive and irregular than the superior, are attached externally the sterno-hyoid, the omo-hyoid, and the thyro-hyoid muscles; and in the middle the thyro-hyoid membrane. To its upper margin the fibres of the *hyoglossus* are attached. Each of the lateral margins is moulded into a convex cartilaginous surface, articulated with the lateral bones.

The lateral bones (*ossa lateralia, cornua*), though longer, are less thick than the body Broad and thick before, with the upper surface concave and the lower convex, narrow behind, they terminate in a round head, tipped with cartilage, to which the thyro-hyoid ligament is attached. At the anterior junction nearly of these with the middle portion, there is attached to the latter on each side a small elongated bone, somewhat hooked. These bones, which seldom exceed the size of a grain of wheat, or rye rather, and which they somewhat resemble in

Special Anatomy.

shape, are articulated to the other two by a true capsular ligament. To their outer surface are attached some fibres of the *genio-glossus*, and to their upper is fixed the stylo-hyoid ligament.

The hyoid bone consists externally of compact, and internally of cancellated tissue, the latter being most abundant in the middle piece. Though composed in the infant and young subject of five portions, the articulations are invariably obliterated by ankylosis in adult life, and they are converted into a single bone. The junction of the middle and lateral portions is effected first, and that of the pisiform bones afterwards.

The cranium in general.

The bones now described, excepting the lower jaw and hyoid, are united immovably, or by *synarthrosis*. The external shape of the cranium is that of an oblong spheroid, or an ovoid, with the small diameter before. Convex in general, it is flattened laterally in the temporal regions, and below in the base. The external surface, smooth and regular above, is marked below by muscular impressions, and penetrated by numerous holes.

The sutures.

The first objects deserving attention are the serrated lines of junction, or what are named the sutures (*suturæ*), which are in general more conspicuous externally than internally, where indeed they are effaced at an earlier period of life than on the outer surface of the scull. The sutures may be most easily understood by tracing them from the sphenoid bone, which may be regarded as the central point of the cranium.

The first line is that which passes transversely across at the junction of the sphenoid with the ethmoid and superior turbinated bones in the middle, and the frontal bone on each side. Concave in the middle, this line bends backward at each extremity, where it follows the outline of the small wings of Ingrassias. It constitutes the transverse or sphenoidal suture.

The posterior margin of the body of the sphenoid bone is marked by another transverse suture, extremely short, and uniting it with the *cuneiform* process of the occipital bone. This, which is early obliterated by the indissoluble union of the sphenoid and occipital bones, is a cartilaginous junction, afterwards ossified, and, though scarcely entitled to the epithet, is named nevertheless the *basilar suture*.

A more distinct one is found in the line between the exterior concave margin of the large wing of Ingrassias and the squamous portion of the temporal bone in the *spheno-temporal suture*. It terminates below at the glenoid fissure, forming an acute angle with a short line between the pyramid and the posterior margin of the spinous process of the sphenoid, named the *petro-sphenoidal*. Above, where it terminates on the parietal bone, a short line, between the outer margin of the large wing of Ingrassias and short spaces of the parietal and frontal bones, is distinguished as the *lateral sphenoidal* or the *spheno-parietal suture*.

This line, produced backwards between the upper margin of the temporal and the lower margin of the parietal bone, constitutes a peculiar form of junction, named the squamous suture (*sutura squamosa*), the temporal, or the temporo-parietal, in which the edge of the former bone is imbricated over that of the latter. In this mode of junction, which is confined to the superior part of the temporal bone, and in which the union of the bones is not secured by dove-tail ossification, but simple imposition, the lateral pressure is effected chiefly by the force propagated from the *zygoma* and the malar bone.

The posterior part, which is united to the posterior-inferior angle of the parietal, and the anterior-inferior margin of the occipital, presents a serrated line, with alternate indentations, which are well marked, but irregular in size. This, which occasionally presents Wormian bones, may be named the *posterior-temporal suture*. The descending portion has been distinguished by the name of *mastoid suture*. Anteriorly, in the base of the cranium, where it passes the jugular notch, the line of junction, which is cartilaginous, is termed the *petro-occipital suture*.

Special Anatomy. Cranium in general.

The sutures now enumerated agree in being found chiefly at the lower region of the cranium, and in securing the junctions of its base. The others to be yet enumerated belong to its superior region, and agree in consolidating and securing the several arches which constitute what may be named the *vault* of the *cranium*.

From the point at which the posterior, temporal, and mastoid sutures unite, a serrated line of junction ascends on each side to the common point at which the occipital and parietal bones meet. From the angular junction formed by the two limbs of this suture, it is known under the name of *lambdoidal* (Λ, *sutura lambdoidalis*); and from its situation it is termed the occipital and occipito-parietal suture. By mutual indentations, which are always distinct, it joins firmly the parietal and occipital bones; and it is the most frequent seat of Wormian bones.

From the angle of the lambdoidal suture a similar serrated line proceeds, uniting the two parietal bones on the mesial plane, with equally distinct indentations. The mode in which this stretches between the lambdoidal and coronal sutures, bearing some remote resemblance to an arrow on the drawn bow-string, has procured it the name of the sagittal (*sutura sagittalis*). In youth and in early life these two sutures are distinct; but in advanced age they are more or less, sometimes entirely, obliterated.

In some craniums the sagittal suture is continued along the frontal bone to the nasal spine, thus parting the bone in two lateral halves. This, which constitutes the proper *frontal* or *median* suture, is the remains of the original separation of the bone.

Lastly, Between the frontal bone before, and the parietal bones behind, is seen a serrated line crossing the cranium transversely, the whole breadth between the two sphenoid bones. This, which is named the *coronal* suture, presents large indentations on each side and small ones in the middle, on the external table, and a converse arrangement on the internal.

By these sutures the bones forming the vault of the cranium are firmly secured; and each bone is made to press against the other so as to augment rather than diminish strength.

The external surface.

The external surface of the cranium may be distinguished into four regions, a superior, an inferior, and two lateral ones.

The superior region, or the vault, is bounded before and behind by the nasal and occipital protuberances, and on each side by the temporal arches. It presents, besides the coronal, sagittal, and lambdoidal sutures, the superciliary arches, the frontal, parietal, and occipital protuberances, and the parietal holes. It is covered by the epicranial muscle and its *aponeurosis*.

The inferior region or base, which may be defined from the occipital protuberance behind to the nasal spine before, is free as far as the pterygoid processes of the sphenoid bone, anterior to which it is joined to the bones of the face.

In the posterior portion are seen the occipital spine and muscular impressions, the occipital hole (*foramen magnum*), the condyloid processes, the anterior and posterior condyloid holes, and the basilar process. Laterally are the digastric groove, the mastoid, styloid, and vaginal pro

Special Anatomy.

Cranium in general.

cesses, and the stylo-mastoid hole, the glenoid cavity and fissure; the jugular hole (*foramen lacerum in basi cranii*), separated by a bony process into an internal part for the *nervus vagus* and the accessory nerve, and an external for the jugular vein; the pyramid, with the carotic canal, and the anterior lacerated hole between its extremity, the basilar process, and the sphenoid bone, closed by fibro-cartilage in the recent subject. Before these objects, and nearly in the same transverse line, are seen the anterior half of the glenoid cavity of the temporal bone, the guttural orifice of the Eustachian tube, the spinous and elliptical holes of the sphenoid (Plate XXIV. fig. 5), and the pterygoid processes.

The anterior portion presents the crest or azygos process united with the vomer and ethmoidal plate, the sphenoidal sinuses, the ethmoidal bone itself, and the nasal spine of the frontal bone; laterally, the anterior surface of the pterygoid processes, the Vidian canal, the round or superior maxillary hole, the temporal and orbitar surfaces of the large wings of the sphenoid bone, the sphenoidal fissure (*foramen lacerum*), the optic holes, and the small wings of Ingrassias; and, *lastly*, the vault and internal wall of the orbit, the former by the frontal bone, the latter by the *os planum* and lacrymal bone.

The lateral regions of the cranium are nearly of an elliptical shape. Each region may be circumscribed by a line drawn from the mastoid process backwards to the union of the temporal and mastoid sutures, then following the semicircular arch of the parietal bone, and the angular arch of the frontal to the *zygoma*, ear-hole, and mastoid process. The objects inclosed in this region are the posterior mastoid hole, the mastoid process, the ear-hole, and the *zygoma*, with a large space, defined by the elevated line extending from the posterior extremity of the *zygoma* upwards to the semicircular arch of the parietal bone, where it is obtuse, and the external angular ridge of the frontal bone, where it becomes acute. To this line, the *zygoma*, and the malar bone, the fascia of the temporal muscle is firmly attached; the muscular fibres adhere to the bone below as far as the line of the sphenoid bone, and pass downwards under the *zygoma*. The whole region, though convex in early life, becomes less so in adolescence, and in manhood and advanced age it is flattened and even hollowed.

The internal surface.

The internal surface of the cranium, lined by the *dura mater*, and marked by cerebral and vascular impressions, is distinguished into the superior region or vault, and the inferior or base.

In the former, which is a regular spheroidal concave, the chief peculiarities are, on the mesial plane, the frontal crest, the sagittal groove for the superior longitudinal sinus, pits for the granules of Pacchioni, and the inside of the sagittal suture, more distinct than the outside; laterally, the upper cerebral regions of the frontal and parietal bones, with their *fossæ*, the coronal suture, and the superior occipital fossæ.

The base is more complicated, and is generally distinguished not only into lateral halves, but into anterior, middle, and posterior regions.

On the median line from before backwards, the objects are,—the blind hole (*foramen cæcum*), for the naso-frontal vessels; the ethmoidal crest (*crista galli*), and vertical plate, with the perforated plate (*e*); the spheno-ethmoidal suture; the transverse groove and olivary process, and optic holes (1 1); the pituitary fossa (*ephippium*) (3); the posterior clinoid processes (4 4); the spheno-occipital junction; the basilar groove for the *medulla oblongata* (6); the occipital hole; and the internal occipital spine and protuberance. (Plate XXIV. fig. 6.)

Of the lateral halves, the anterior or frontal region is bounded before by an indistinct curved line, formed by the vertical with the horizontal table of the frontal bone, and behind by the sphenoidal arch. In this, which is named the *frontal fossa*, the anterior lobe of the brain is lodged; while the sphenoidal arch enters the fissure of Sylvius.

Between the sphenoidal arch before, and the posterior margin of the temporal pyramid behind, is contained a cavity shaped like a spherical segment. In this, which may be named the spheno-temporal hollow (*fossa spheno-temporalis*), the anterior part of the posterior lobe of the brain is lodged. In this cavity also are seen the sphenoidal fissure; the round or superior maxillary hole; the oval or inferior maxillary hole; the spinous or meningeal hole, with the meningeal groove; the anterior or spheno-temporal fissure (*foramen lacerum anterius basis cranii*); the inner end of the carotic canal; the pyramidal groove; and the semilunar fossa for the Gasserian ganglion. (Plate XXIV. fig. 6.)

Between the temporal pyramid and the internal occipital spine is contained the posterior or temporo-occipital hollow (*fossa temporo-occipitalis*), which is further subdivided into two cavities, the cerebral above, and the cerebellic below. From the posterior margin of the pyramid to the transverse occipital ridge, a fold of the *dura mater*, stretched horizontally, separates the temporo-occipital cavity into a superior for lodging the posterior lobe of the brain, and an inferior or cerebellic for lodging the lobes of the cerebellum. In the anterior or cerebellic division is seen the posterior surface of the pyramid, with the internal auditory hole, the orifice of the cochlear aqueduct, the groove for the lateral sinus terminating in the jugular opening, the groove of the inferior petrous sinus, and the mastoid hole and suture. The only object behind is the posterior cerebral *fossa*, traversed by the lambdoidal suture.

Developement and dimensions at different periods.

In the fœtus the cranial bones inclosed between the *pericranium* and *dura mater*, which are thick, soft, and vascular, are incomplete shells not in contact with each other, with prominent and rather thick ossific centres, from which the osseous radii diverge, and terminate in thin, ciliated margins. At birth, and for some weeks after, though ossification is far advanced, the margins of the bones are incomplete, so as to form the open spaces denominated fontanelles. Of these there are six at the period of birth; the anterior or rhomboidal between the frontal and parietal bones; the posterior or triangular between the occipital and parietal bones; two lateral anterior between the parietal, sphenoidal, and temporal bones; and two posterior lateral between the parietal, temporal, and occipital bones, both of irregular shape. At these points the motions of the brain are distinctly felt.

At the same time the bones have not yet acquired their serrated margins, so that the places of the sutures, which are not yet formed, are occupied by narrow grooves between the cranial bones. As ossification advances, however, their fimbriated margins extend, and mutually meeting, are prolonged so as to be indented into each other by alternate notches and processes. At the same time the bones acquire thickness, so that a distinct space is perceived between the external and internal surface of each. The alternate processes and notches thus acquire firmness, and are immovably dovetailed into each other. In this manner the anterior angles of the parietal bones unite with the frontal, and between the posterior ones the apex of the occipital bone is gradually mortised.

In some instances, however, where the ossific centre of the original bone appears deficient in energy, or tardy in progress, a new centre may be developed in the line of

Special Anatomy.

Cranium in general.

junction, while the bones are still much apart. Thus, between the occipital and parietal bones, or between the occipital and temporal bones, may be developed new centres, from which ossification advances, as from the principal points, towards the circumference; and by the successive deposition of bony matter, the margins begin to meet those of the primary bones. The process of mutual indentation takes place exactly in the same manner as with the primary bones; and by this means secondary bones are formed in the lines of the sutures.

The period at which the cranium is entirely ossified varies in different individuals. In general the anterior or fronto-parietal fontanelle, which is the largest, is ossified at the end of the 18th or 20th month, while the anterior and posterior lateral are closed at an earlier period. In some instances, however, between the parietal and frontal bones a small space is left till the 6th or 7th year; and in many persons the part continues depressed and tender for the greater part of life. The sutures are completed at the same time, and are always distinctly formed by the 10th or 11th year. A few years after, they become more consolidated, and, as the bones acquire thickness and density by the compactness of the external and internal tables, are firmly wedged into each other. The spheno-basilar junction generally remains soft and separable till adult age, when by its union the sphenoid and occipital bones are converted into a single piece. Some time afterwards the sphenoid is united with the ethmoid, the two parietals are converted into one, and occasionally one or both are united to the frontal bone. In advanced age many of the sutures disappear entirely, at least in one surface of the cranium, generally the internal first; and the cranium would be converted into a single bone if life were continued sufficiently long.

In shape and dimensions the cranium varies at different periods of life. After ossification is completed in the child, the prominence of the ossific points, which continue more or less conspicuous till manhood and the formation of the frontal sinuses, gives it a cubo-spheroidal shape. Its section is an oval or two hemispheroidal segments, the anterior being the smallest. At this period the parietal tuberosities and the occipital eminence are prominent, the frontal bone is vaulted, and the high open forehead communicates to the countenance an expression of beauty and simplicity which are always associated with the early and middle periods of life. In the progress of years, however, these prominences become less distinct, partly by the operation of muscular action, partly by the uniform rising and swelling of the margins of all the bones; and the anterior upper and posterior part acquires a uniform spheroidal or vaulted appearance, while the lateral regions are flattened by the action of the temporal muscle. The occipital region also below the spine is flattened, and occasionally excavated; so that while the spine is prominent and unciform, the base is excavated, and overhung by the mastoid processes and the semilunar ridges. The aged scull is thus distinguished by a general rotundity or ovoidal character, unless in the temples, which are flat and hollow; and the convex but occasionally depressed forehead indicates in some degree the transition from youth to age.

The dimensions of the cranium are estimated from its diameters, longitudinal, transverse, and vertical. The first, which extends from the *foramen cæcum* of the frontal bone, is about five inches at an average. The largest transverse diameter, which extends between the bases of the temporal pyramids, is about 4½ inches; and a smaller one between the extremities of the two small sphenoidal wings is about 3 inches and 9 lines. The longest vertical diameter, which is between the anterior margin of the occipital hole and the middle of the sagittal suture, varies from 4 inches to 4 inches and 3 lines. From these measurements it results, that the most capacious part of the scull is nearly at the union of the two anterior thirds with the posterior, viz. the level of the occipital hole and basilar groove; and that the ovoidal or oblong-spheroidal is the most general shape. The variations from this shape are found chiefly in the vault, which may be flattened, oblong, cuboidal, or conical.

Varieties.

The Asio-European may be regarded as the best and most symmetrical shape, and to this most of the European *crania* belong. According to Soemmering, the Belgic scull is the most oblong-globular, the German and Italian spherical, and the Turkish the most spherical of the European. In this country the most usual shape is the oblong-spheroidal, especially among the inhabitants of England. Among an extensive collection of sculls preserved in the Museum of the University of Edinburgh, and believed to be chiefly Parisian, the prevalent shape is the oblong-spheroidal, and the globular, or the general spherical shape, with large transverse diameter approaching to the longitudinal. From the delineations given by Sandifort (*Museum Anatomicum*, tom. ii.), the English appears most prominent in the occipital region, the French the most vertical forehead, and the Italian most elevated in the vertical region, and most prominent between the parietal tuberosities. The scull of the Swede approaches the cubo-spheroidal, and that of the Russ is distinguished chiefly for the vertical front, considerable transverse width, and large cheek-bones. The latter appear not to be peculiar to the Scotish cranium.

Of the Asiatic craniums, the Tartar has the forehead large, not much arched, the occipital region large, the nasal bones descending straight from the frontal, the upper maxillary bone slightly overhanging the lower, and the chin prominent. That of the Calmuc has the vertical, occipital, and parietal regions prominent, the frontal bone and face flattened, the cheek-bones large, and the alveolar arches and jaws broad and prominent. The Mongolian is distinguished by the narrow forehead, flattened and rather depressed glabellar and nasal regions, great facial width between the cheek-bones, and prominent upper jaw

From the observations of Blumenbach and Soemmering it results, that the ancient Egyptian or Coptic head, as exemplified in mummies, belongs to the European class of craniums. The negro head, on the contrary, is distinguished for its oblique forehead, compressed sides, prominent jaws, general wedged shape, and large size compared with the rest of the skeleton. For more minute information on these varieties, the reader will consult with advantage the work of Soemmering (tom. i.), and the *Decades Craniorum* of Blumenbach.

The face generally.

In shape the face forms an irregular hexahedron, with a large excavation at its lower region for the mouth and pharynx. Its anterior surface is trapezoidal, with the short side below; its sides trapezoidal, with the short side formed by the posterior margin of the maxillary *ramus*; and its upper surface is an oblique parallelogram.

The greatest transverse diameter is between the zygomatic angles of the cheek-bones, varying from 4½ to 5 inches; its smallest at the symphysis of the lower jaw, from 1½ to 2 or 2¼ inches; and on the extent and prominence of which depends the general oval shape of the countenance. The height, measured from the glabella to the triangular process of the lower jaw, varies from 4½ to 4 inches 9 lines.

The direction of the face varies according to the position of the lower jaw. When this is horizontal, the facial plane forms with it an angle of 60°, or deviates 30° from

Special Anatomy. Cranium in general.

the vertical plane; and in some tribes, as the negro, this deviation is still greater. A more important character, however, is believed to be found by determining the direction of the face in relation to that of the cranium, or ascertaining what Camper denominates the *facial angle.* This he proposes to fix by drawing one line from the fronto-nasal protuberance to the spine of the upper maxillary bone,—the *facial* (*linea facialis*); another transversely between the external ear-holes; and from the latter a third line (*linea horizontalis*), drawn at right angles to meet the first. The angle thus formed by the facial and horizontal lines, which is termed the facial, indicates the comparative prominence of the cranium and face. In European heads generally it is about 80°; in the negro it is not above 70°; and in the Mongolian, which is intermediate, it is about 75°. The effect of this angle in giving the countenance intellectual expression, the nearer it approaches to the rectangle, was known to the ancients. In many of the busts of heroes it is almost 90°, and in those of divinities 100°; and as we know that this is much more rectangular than any specimen of the human scull furnishes, it may be inferred that it is imaginary.

It may be further observed, that in the infant the facial angle approaches to 90°, in consequence of the small relative developement of the face. Towards boyhood and puberty, when the face acquires greater size and prominence, it diminishes to 85° and 80° successively. (Cuvier, Bichat.)

The face is subdivided into cranial, facial, zygomatic, and palato-maxillary regions. It is unnecessary to enumerate again the objects found in these several regions; but it is requisite to consider shortly the cavities which are formed by the cranio-facial bones. They consist of the nasal cavities, the orbits, the tympanal cavity, and the palato-maxillary region. These cavities are distinguished by the following circumstances. All of them communicate mutually, and are covered by fibro-mucous membrane, also continuous. In each of them is lodged one of the organs of special sensation; and each communicates with the cranial cavity by openings, through which nerves always, and sometimes vessels, are transmitted. Lastly, these cavities may be regarded as the points by which the cutaneous surface communicates directly with the mucous membrane of the gastro-pulmonary organs.

The nasal cavities (*cavum nasale, nares*), of an irregular quadrilateral shape, consist of four regions; the upper, the lower, and two lateral. The first is bounded before by the nasal bones, behind by the sphenoidal cells, with which it communicates, and above by the cribriform plate; while its lower limit is a line uniting the inferior margins of the lateral portions of the ethmoid bone. This is parted by the vertical plate of the ethmoid bone into two halves, which are the two superior passages (*meatus superior*). The lower region is bounded below by the palato-maxillary plate; on the sides by the maxillary, palate, and inferior turbinated bones; above by a plane uniting the lower margins of these bones, and is parted into two by the vomer, which opens before at the nasal notch of the maxillary bones, and behind at the posterior margin of the palate bones. This constitutes the lower passage (*meatus inferior*), at the anterior extremity of which the nasal canal opens. The anterior part of the region presents on the mesial plane a vertical triangular notch between the middle ethmoid plate above and the *vomer* below, occupied in the recent subject by the cartilaginous *septum* of the nose. The middle and lateral regions, which communicate before by this notch, are separated behind by the ethmoid plate and vomer, and are bounded above by the ethmoidal turbinated bone, and below by the maxillary turbinated bone. This constitutes the middle canal (*meatus medius*), in which the frontal and maxillary sinuses open.

Special Anatomy. Cranium in general.

These cavities communicate freely with each other; and their parietes are covered by continuations of the same general fibro-mucous membrane. Their use appears to be to increase the extent without adding to the weight of the facial bones, to afford great superficial extent to the nasal membrane as an organ of smell, and to afford a sonorous vault to the organ of voice.

These cavities, and their appendages, do not exist in the fœtus, nor for some time after birth. The ethmoidal and sphenoidal are early formed; and the maxillary sinus begins to be manifest some months after birth. After the primary dentition they enlarge, and rapidly after the second; and towards the approach of puberty, when the maxillary tuberosity is formed, they increase, and speedily attain their natural capacity.

The orbits are two cavities, one on each side of the mesial plane, of the shape of a quadrilateral pyramid, with the apex towards the cranial cavity, and the base anteriorly. Each orbit presents a *vault* formed by the frontal bone, a *floor* formed by the superior maxillary, an internal wall formed by the palate bone, ethmoid, and lacrymal, and an external wall formed by the malar and sphenoid bones. The two internal walls are nearly parallel,—an arrangement which renders the axes of the orbits convergent backwards, and indefinitely divergent before. The vault of the orbit is so thin, that a pointed instrument easily penetrates; and a thrust in the eye is invariably attended with severe, generally fatal, injury to the base of the brain. The base of the orbits is oblique, with the temporal margin behind the plane of the nasal, making the eye more exposed without than on the mesial side. The inner or nasal margin presents the upper orifice of the nasal canal. At the posterior extremity of the inner wall is the optic hole; at the apex is the sphenoidal fissure, which forms nearly a right angle with the spheno-maxillary fissure below; and the floor is traversed by the superior maxillary fissure and canal. The apex of the orbit is occupied by the optic nerve, the third and fourth pair, the ophthalmic branch of the fifth, and the sixth; and the origins of the six muscles of the eyeball, with interposed fat. The base is occupied by the eyeball, surrounded with the tendinous extremities of the muscles, the lacrymal gland at the external region of the vault, and the lacrymal sac in the anterior depression of the nasal margin. To its margins are attached the palpebral and the orbicular muscle. Each orbit communicates with the nasal cavities by means of the nasal duct.

The tympanal cavity, formed in the temporal bone, communicates by the Eustachian tube with the posterior part of the nasal and palato-maxillary cavities. Its further examination belongs to a subsequent head.

The palato-maxillary cavity is formed by the palatine vault above, the alveolar arches and teeth before, by the lower jaw before and laterally, and behind by the basilar process of the occipital bone and the pterygoid processes. It is very irregular in shape, and consists of two regions, the palato-maxillary proper and the pharyngeal. The principal objects deserving notice are the incisive duct in the palatine vault, for the naso-palatine nerves; the pterygo-palatine canal at its posterior angles, for the pterygo-palatine branches; and the posterior opening of the nasal cavities. The vault is covered by periosteum and mucous membrane, with the *uvula* or soft palate suspended at its posterior margin; and the space inclosed by the lower jaw contains the tongue, attached to the hyoid bone, sublingual and submaxillary glands, and is completed by membrane, muscles, and integuments.

Special Anatomy.

§ 6. *The Thoracic Extremities.*

Thoracic extremities.

The superior or thoracic extremities consist of the shoulder, the arm, the fore-arm, the wrist, and the hand.

The shoulder consists of two bones,—the *scapula* or shoulder-blade, and the clavicle or collar-bone.

The scapula.

The *scapula* is a triangular bone occupying the posterior part of the chest, having a dorsal and a costal surface, and a superior, a vertebral, and an axillary margin.

The dorsal or posterior surface (*dorsum*) is divided by a transverse elevated spine into two parts, the *fossa supraspinata* for the *supraspinatus* muscle, and the *fossa infraspinata* for the *infraspinatus* muscle. The latter is concave above, convex in the middle, and concave towards the axillary or external margin (*costa*), from which it is separated by a round line or crest for the attachment of the fascia which separates the *infraspinatus* from the *teres major* and *minor*. Between this crest and the axillary margin above is a convex surface, of a triangular shape, with the apex above, for the attachment of the *teres minor*, and below a flat quadrilateral surface for the *teres major*.

The spine is a triangular-shaped eminence, rising obliquely from the upper fourth of the dorsal surface; low at the vertebral, elevated at the axillary margin, where it terminates in a broad, flat surface, also triangular, named the *acromion* or shoulder-top. In the posterior margin of the spine may generally be distinguished two surfaces separated by a ridge. Above the ridge the *cucullaris* is fixed; below, part of the deltoid is attached; and between is a common aponeurosis. The ridge is biparted towards the *acromion*, leaving an interval covered by periosteum and integuments only. The anterior part of the acromion presents a cartilaginous facette, for articulation with the acromial end of the clavicle. To its posterior and external margin the deltoid is attached, and to its tip the acromio-coracoid ligament is fixed.

The costal or anterior surface is of a triangular shape, with the apex below, generally concave, but subdivided into smaller spaces by two or more oblique ridges, to which intermuscular *fasciæ* are attached. This surface, which is the *subscapular fossa* (*venter*), lodges the belly of the subscapular muscle, the fasciculi of which are interposed between the aponeurotic ridges. Near the vertebral margin is an irregular surface, to which, and also to the margin, the *serratus magnus* is attached.

The superior margin (*costa superior*) is thin and pointed behind, where the *levator* and omohyoid muscles are attached, and becomes sinuous externally, with a notch converted by a ligament into a hole for the transit of the suprascapular vessels and nerves. The inner or axillary extremity terminates in an elevated hooked process, the coracoid, to the tip of which are fixed the coraco-clavicular ligament, and the united origin of the short head of the *biceps flexor* and the *coraco-brachialis*, to the anterior margin the small pectoral, and to the posterior the acromio-coracoid ligament.

The vertebral or posterior margin (*costa posterior*, *basis* of some authors) is thin, and ascends straight to the spine, giving attachment to the *rhomboideus*; then bends forward, and forms with the superior an angle, to which, as also to the edge now mentioned, the *levator* is fixed.

The axillary margin (*costa axillaris*, sometimes *inferior*) is round and broad above, and narrow below. It presents above, first the glenoid cavity, round at its lower margin, angular above, hollow, covered by cartilage and synovial membrane for receiving the head of the *humerus*. At the angular point above is a surface for the attachment of the long head of the *biceps flexor*, and the lower margin presents two tubercular eminences for that of the long head of the *triceps extensor*. Below this are fixed the *teres minor*, the *subscapularis*, and the *teres major*. The *latissimus dorsi*, passing over its lower angle, binds it down.

The scapula consists chiefly of compact bone, with little cancellated matter interposed. In the subscapular *fossa* this becomes completely absorbed, rendering the bone thin and translucent, sometimes perforated. The spine, processes, and angles contain cancellated matter. It is formed from one part for the body of the bone, with *epiphyses* for the coracoid process and the margins. Nutritious holes are generally found in the angle formed by the spine with the body, and in the axillary margin.

Clavicle or collar bone.

The collar bone or clavicle is a cylindrical bone, alternately incurvated like an *ſ*, placed at the upper part of the chest, between the sternum and acromion of the scapula. It has therefore two extremities, a sternal and acromial, with intermediate body.

The *sternal* end is triangular, cartilaginous, concave and convex in opposite directions, surrounded by ligamentous insertions. The *acromial* end is flattened and recurved, presenting a lunated surface for articulation with the acromion.

The body, with the shape of a triangular prism at the sternal end, is rounded above for the attachment of the clavicular portion of the sterno-mastoid muscle, and presents below a rough surface for the costo-clavicular ligament, and a sinuated line for the subclavian muscle. Towards the acromial end, where it is flattened above and below, it presents before, a surface for the attachment of the large pectoral and deltoid muscles; behind, another for the *cucullaris*; and below, a prominent oblique crest for the coraco-clavicular ligaments.

Compact in the middle, and cancellated at its extremities, the clavicle is developed from a single point.

The arm-bone.

The arm-bone or *humerus* (*os brachii*) is a long cylindrical bone, divided into head or scapular end, cubital or lower end, and shaft or body.

The head presents three eminences, the articular head, the anterior tuberosity, and the external tuberosity. The first, which is hemispherical, incrusted by cartilage and synovial membrane, with the axis oblique to that of the bone, and articulating with the glenoid cavity of the scapula, is separated from the bone by a narrow depressed line named the neck (*collum*), in which is fixed the margin of the scapulo-humeral capsular ligament. The second is a small, pointed, sometimes bifid eminence, to which the tendon of the *subscapularis* is attached. In the external tuberosity are distinguished three facettes, to the upper of which the tendon of the *supraspinatus*, to the middle that of the *infraspinatus*, and to the posterior the tendon of the *teres minor*, are inserted. Between the anterior and the external tuberosity is a longitudinal groove named the *bicipital*, for the transit of the long head of the *biceps flexor*.

The cubital or lower extremity is flattened transversely, and moulded into different eminences and depressions. Internally is the inner or ulnar condyle, large and prominent, for the attachment of the internal lateral ligament, and a tendon common to the *pronator teres*, *palmaris longus*, *flexor sublimis*, *radialis internus*, and *ulnaris internus*. Externally is the outer or radial condyle, to which are attached the external lateral ligament, and the tendon common to the supinators and extensors, viz. *supinator longus* and *brevis*, *anconeus*, *radialis externus*, *ulnaris externus*, and *extensor communis*. Between these is an articular surface covered by cartilage, moulded into the small head which moves in the cavity of the *radius*,—a groove corresponding to the margin of the latter; the semicircular crest interposed between the *radius* and *ulna*,—

Special Anatomy.

Thoracic extremities.

another groove rather larger, in which the prominence of the sigmoid cavity is lodged; and the trochlear or pulley-like eminence, which is received in the internal part of the sigmoid cavity, and the size of which renders the inner side of the humerus larger than the outer, and gives it the oblique direction when placed on the horizontal plane. Before is a superficial pit for the coronoid process of the *ulna* during flexion of the fore-arm, and behind is a deep one for receiving the *olecranon* during extension.

The shaft is not cylindrical, but prismatic, consisting of three surfaces, bounded by an equal number of lines. The first line, which descends from the anterior tuberosity, and, winding to the side, terminates on the ulnar condyle, is anterior above, where the tendons of the *latissimus dorsi* and *teres major*, and the short head of the *triceps*, are attached, but becomes internal-lateral below, where an intermuscular aponeurosis is fixed. The second, which descends from the fore-part of the large tuberosity to the anterior articular pit, is anterior throughout, and gives attachment above to the large pectoral muscle, at the middle to the deltoid, and below to the *brachialis externus*. The third line, which descends from the back of the great tuberosity to the external or radial condyle, is posterior above, where the *triceps* is fixed, but external below, where the intermuscular aponeurosis and the *supinator longus* are attached.

Of the three surfaces, the first, which is anterior and internal, presents above, the bicipital groove, covered by periosteum and synovial membrane for the long head of the *biceps*; in the middle, the medullary hole and insertion of the *coraco-brachialis*; and below, a surface covered by part of the *brachialis internus*. The second, which is external, is covered above by the deltoid, below by the rest of the *brachialis*, and in the middle presents the deltoid tuberosity for the insertion of its tendon, and below this an oblique sinuosity traversed by the radial nerve. The third, which is posterior, gives attachment above to the *triceps*, and below is merely covered by that muscle.

The *humerus*, cancellated at its extremities, and compact in the shaft, is ossified in three parts; one for the latter, and one for each of the former.

The ulna.

The *ulna* or cubit (*cubitus*) is a long bone placed at the inside of the fore-arm, articulated above with the *humerus*, below with the *carpus* or wrist, and laterally with the *radius*. Its superior or humeral extremity consists of two eminences, and an intermediate semilunar or crescentic cavity. The first is a large head named the *olecranon* (ωλενης κρανον, *ulnæ caput*, or elbow; *processus anconeus*, *ancon*); irregular above, with a small space behind, where the tendon of the triceps extensor is fixed; concave and cartilaginous before, where it forms part of the sigmoid cavity. The second is a broad, thin-edged process, prominent before, about half an inch below the olecranon, the upper surface of which is cartilaginous, and completes the sigmoid cavity; the lower surface is rough for the *brachialis internus*, some fibres of the *pronator teres*, the *flexor sublimis*, and the internal ligament of the humero-cubital articulation. At the outside, and continuous with the sigmoid cavity, is a small semicircular cartilaginous surface—the *small semilunar*—for articulating with he head of the *radius*.

The lower or carpal extremity presents a cartilaginous surface, shaped like a circular sector, the circular margin being bent upwards, so as to form a circular surface for the inner articular surface of the *radius*, while from the centre of its radii arises a pointed process named the styloid, to the tip of which the external ligament of the radio-carpal articulation is fixed. Between the styloid process and sectorial surface is a depression, to which is fixed the fibro-cartilage of the joint; and behind and without the styloid process is a longitudinal groove for the motion of the tendon of the *ulnaris externus*.

The shaft has the shape of a trilateral prism, except at the lower extremity, where it becomes cylindrical. Of the three lines by which the surfaces are bounded, the external or radial, which is strongly marked, and sharp at the middle, extends from the posterior tip of the small sigmoid cavity to about two inches above the lower end, and gives attachment to the interosseous ligament. The second, internal or ulnar, which is obtuse, descends from the inner edge of the coronoid process to the inside of the styloid, and gives attachment above and in the middle to the *flexor profundus*, and below to the *pronator quadratus*. The third, posterior, obtuse above and below, sharp in the middle, extends from the olecranon to the outside of the styloid process, and gives attachment to an aponeurosis.

Of the surfaces inclosed by these lines, to the anterior, which is concave, and contains the medullary hole, the *flexor sublimis* is attached above, and the *pronator quadratus* below. The inner is covered above, where it is broad, by the *flexor profundus*, and below by the integuments. The posterior or radial is parted by a line into two spaces, to the larger of which are fixed the *anconeus* and *ulnaris externus*, and to the smaller the *supinator brevis*, *extensores pollicis longus et brevis*, the *abductor pollicis*, and *extensor indicis*.

The radius.

The *radius* is a long bone, rather shorter than the *ulna*, forming the outer bone of the fore-arm, articulated above with the *humerus*, below with the carpus, and at the inside with the *ulna*.

The upper extremity consists of a circular cartilaginous head, concave for receiving the small head of the *humerus*, with a cartilaginous surface on its inner or ulnar side for articulating with the small sigmoid cavity of the ulna, and a rough one for the annular ligament on the outside. Below this the bone is contracted and forms the neck of the radius, and again swells before into a large rough prominent tubercle, to which the tendon of the *biceps flexor* is fixed, and which is therefore named the *bicipital tuberosity*.

The lower extremity, which is double the size, forms an extensive surface for articulation with the scaphoid and semilunar bones of the *carpus*, continuous on the ulnar side with a small cartilaginous surface for articulation with that of the *ulna*, bounded without by the styloid process, a rough triangular eminence, to which is fixed the external ligament, and bounded elsewhere by a rough margin for ligamentous insertions. The posterior part of this end presents two eminences inclosing a wide hollow, separated by a small eminence into two grooves,—an inner or ulnar, large for the tendons of the *extensor communis* and the *extensor proprius indicis*, and an outer or radial for the *extensor longus pollicis*. Between the middle eminence and the styloid process are two other grooves,—the anterior for the *abductor magnus* and the *extensor brevis* of the thumb, and the posterior for those of the *radiales externi*.

The shaft or body, which is thin and round above, prismatic in the middle and below, presents three surfaces inclosed by an equal number of lines. Of the latter, the inner or ulnar descends from the inner margin of the bicipital tuberosity, sharp and prominent, to the small inner articular surface, and gives attachment to the interosseous ligament. To the outer, which descends from the outer margin of the tuberosity, obtuse, to the base of the styloid process, the *flexor sublimis*, *pronator quadratus*, and *supinator longus* are attached. The third, also obtuse, is indistinct to the second third of the bone,

Special Anatomy. Thoracic extremities.

whence it proceeds to the middle tubercle of the carpal extremity.

The anterior surface, which is hollow above, presents the medullary hole and the attachment of the *flexor longus pollicis* below that of the *pronator quadratus*. The posterior, hollowed in the middle, corresponds to the *supinator brevis*, the extensors, and *abductor pollicis*, which are attached to it; and the common extensors, *extensor proprius indicis*, and *extensor pollicis*, by which it is simply covered. The external surface, which is rounded, is covered above by the *supinator brevis*, in the middle by the *pronator teres*, which are attached to it; and below by the radial extensors (*radiales externi*), which merely glide over it.

The *ulna* and *radius* consist of cancellated structure in the *epiphyses*, and compact inclosing cancelli in the *diaphyses*, and are each ossified in three points.

These two bones are mutually connected by a broad web of periosteum continued from that of the bones, and named the *interosseous* ligament, the principal use of which is to enable the radius to roll laterally in the motions of pronation and supination on the *ulna*, and to give attachment to muscles without adding to the weight of the fore-arm by intermediate bone.

The bones of the hand consist of those of the *carpus*, the *metacarpus*, and the *phalanges*.

The carpal bones.

The *carpus* consists of eight short and irregular-shaped bones, arranged in two rows. Those of the first are the scaphoid or navicular (*os scaphoides, os naviculare*), the semilunar (*os lunatum*), the cuneiform or trilateral (*os triquetrum*), and the pisiform or lenticular (*os orbiculare, os pisiforme*). Those of the second row are the trapezal (*trapezium*), the trapezoidal (*os trapezoides*), the large bone (*os magnum, os capitatum*), and the unciform bone (*os unciforme, os hamatum*).

Of these bones, which it would be tedious to describe minutely, it is enough to say, that their names are intended to indicate their shape; that they are connected mutually by cartilaginous surfaces, so as to allow the gliding motion only; and that, besides periosteum, they are invested by ligaments which maintain them in their position, and tend to strengthen and consolidate the wrist, as the basis of support for the hand and fingers.

By the upper articular surface of the scaphoid and semilunar bones, the *carpus* is connected to the lower extremity of the *radius;* while the upper surface of the trilateral bone is contiguous to the fibro-cartilage of the radio-carpal articulation, and the upper surface of which is in contact with the lower articular surface of the *ulna*. The pisiform bone, which is attached to the anterior surface of the latter, and thus projects before the plane of the other bones into the hand, may be regarded as a sesamoid bone, which serves as a point of insertion to the tendons of the *flexor carpi ulnaris* above, the fibres of the *adductor* of the little finger below, and those of the anterior carpal ligament before.

The inferior surface of the navicular bone is articulated at once to the superior surfaces of the *trapezium* and *trapezoides*. The palmar or anterior surface of the former presents a small groove, in which moves the tendon of the *flexor carpi radialis*, bounded on the outside by the pyramidal process, to which the annular ligament is attached. The *os magnum*, which is articulated above with the semilunar bone, on the radial side with the scaphoid and trapezoidal, below with two metacarpal bones, and on the ulnar side with the unciform bone, is thus wedged firmly like a central base between the others, and contributes much to the solidity of the carpal articulations. The unciform, which is placed at the inside of the range, and is articulated above with the lunar and cuneiform, laterally with the scaphoid, and below with the two inner metacarpal bones, is distinguished by the unciform process rising from its palmar surface, to which part of the *abductor* and *flexor brevis minimi digiti* and the annular ligament are attached, and which, stretched between this and the pyramidal process of the *trapezium*, form a species of arch over the flexor tendons.

The carpal bones consist of cancellated tissue, invested by a thin pellicle of compact bone. In the fœtus and infant they are composed chiefly of brown-coloured, callous substance, homogeneous, but without the smallest trace of bone. Their penetration with this substance takes place about eighteen months or two years after birth.

The metacarpal bones.

The *metacarpus* is usually said to consist of five bones. This is correct so far as situation goes; but one of these bears little resemblance either in shape, connection, or purpose with the other four. It appears, therefore, more natural to restrict the name of *metacarpal* to the four bones which support the digital phalanges, than to extend it to the thumb, the first bone of which is to be regarded as a *phalanx* only.

The four metacarpal bones agree in having trapezoidal heads, cylindrical bodies with an elevated longitudinal line before, and rounded convex lower ends for moving on the concave articular surfaces of the phalanges.

Besides the upper trapezoidal surfaces for articulating with the trapezoidal, large, and unciform bones, the lateral margins are provided with facettes, the first and fourth on one side only, the mutual, the second and third, on both, for articulation with each other. In this manner the metacarpal bone of the index finger is articulated above to the trapezoidal and large bone, and on the inside to the metacarpal bone of the middle finger; the latter is articulated above to the large bone, and on the one side to the index metacarpal bone, on the other to that of the ring finger; while the latter and the metacarpal bone of the little finger are articulated above to the unciform bone and to each other.

The bodies of the metacarpal bones are slightly incurvated before, and form a hollow which corresponds with the palm. In their intervals are contained the *interossei* muscles, the internal at the volar, the external at the dorsal surface. The anterior surface is covered by the flexor tendons, the *lumbricales*, and the palmar fascia. The dorsal surface, which is convex in general, is covered by the extensor tendons.

The index metacarpal bone has attached to its radial margin the first dorsal *interosseus*, to its ulnar, before, the first palmar *interosseus*, and behind the second dorsal *interosseus;* while to its upper anterior extremity the *radialis internus* is inserted, and to the same extremity behind the *extensor radialis longior*.

To the second or middle metacarpal bone, besides the palmar *fascia* and the second and third *interossei*, the *adductor pollicis* and *flexor brevis* are attached to the palmar surface; and the *extensor radialis brevior* is inserted into its dorsal surface.

The fourth or small metacarpal bone, besides the palmar fascia and the third palmar and fourth dorsal *interosseus*, gives insertion by its dorsal surface to the *extensor carpi ulnaris*.

The *phalanges* or bones of the fingers are fifteen small longitudinal bones placed vertically on each other, three to each finger; or forming ranges distinguished into metacarpal, middle, and unguinal, the first row being the longest, the second shorter, and the third or unguinal the shortest.

Special Anatomy.

The phalanges.

The metacarpal *phalanges* agree in having the upper extremities shaped like rounded cubes, with concave cartilaginous surfaces for receiving the lower extremities of the metacarpal bones, and tubercular sides for the attachment of the lateral ligaments. The upper ends of the middle and unguinal are moulded into two cartilaginous cavities with an intermediate ridge, with lateral tubercles for the lateral ligaments. The lower extremities of the metacarpal and middle *phalanges*, which are smaller than the upper, are rounded and separated by a small groove into two condyles, which are received into the cavities of the upper ends. The lower extremities of the unguinal phalanges, which terminate the fingers, are flattened antero-posteriorly, and moulded into crescentic tips (*lunulæ*) transversely.

The bodies of the metacarpal and middle phalanges are convex behind, and have a surface flat before, bounded on each side by a sharp marginal line, and taper gradually from above downwards. Those of the unguinal phalanges, excepting that of the thumb, are convex before as well as behind. The palmar surface of the metacarpal phalanges is covered by the flexor tendons, which in the superficial muscle are inserted into the anterior and upper part of the middle phalanx, while those of the deep-seated flexor are inserted into the upper anterior part of the unguinal phalanx. The first phalanx of the thumb, which is generally considered as a metacarpal bone, has the *abductor magnus* inserted into its upper extremity, and the *opponens* and *flexor brevis* into its body. The dorsal surfaces are covered by the extensor tendons, which, with those of the *lumbricales* and *interossei*, are inserted into the middle phalanges.

The metacarpal and phalangeal bones are compact, with cancellated extremities, and are ossified in three points.

Connections. Shoulder-joint.

The bones now enumerated are connected so as to admit of motion to various extents. The *humerus*, articulated with the glenoid cavity of the *scapula* by a capsular ligament, while the long head of the *biceps* serves the purpose of a round ligament, admits of motion in every direction,—flexion, extension, abduction, adduction, circumduction, and rotation. The humero-cubital articulation, which is secured by two lateral ligaments, admits of extension and flexion only; but in any position of the *ulna* in relation to the humerus, the *radius* rolls on the former, so as to produce those motions of the wrist and hand which are denominated *pronation* or *internal rotation*, and *supination* or *external rotation*.

Elbow-joint.

Wrist and finger joints.

The carpal bones are articulated chiefly with the *radius*, so as to admit of flexion and extension, adduction and abduction, and even some degree of circumduction and rotation. The metacarpal bones are limited in motion. The metacarpal phalanges admit of flexion and extension, abduction and adduction, circumduction and rotation; while those of the middle and unguinal range are confined to flexion and extension. The precision, nevertheless, of which these motions are susceptible, with the numerous modifications which they undergo in combination with the opposable powers of the thumb, and the nicety and delicacy of tact inherent in the skin of the fingers, are the means from which the human hand derives its remarkable aptitude for all the mechanical arts, and all operations requiring manual dexterity. By the combination almost endless of a number of simple motions, so many complex motions are produced, that it is difficult to set limits to the degree of perfection which the hand and fingers, as an organ of prehension, may attain.

The bones of the pelvic extremities.

§ 7. *The Bones of the Pelvic Extremities.*

The bones proper to the lower or pelvic extremities are, the thigh-bone (*femur*), the shin-bone (*tibia*), and leg-bone (*fibula*); with the knee-pan (*rotula, patella*), seven tarsal bones, four metatarsal bones, and 15 phalanges.

The thigh-bone.

The thigh-bone (*femur, os femoris*) is the largest, thickest, strongest, and heaviest bone of the skeleton.

The upper or iliac extremity consists of a head, neck, and two tuberosities named *trochanters*. The head is globular, incrusted by cartilage and synovial membrane, unless at its internal point, where there is an irregular depression for the insertion of the round ligament, and is lodged in the cotyloid cavity (*acetabulum*). It is situate internally in relation to the shaft; and its axis, which forms with that of the latter an obtuse angle, variable in extent according to age and sex, is represented by that of the neck, a contracted cylinder of bone, varying in length according to the same circumstances, flattened before and behind, presenting numerous vascular holes, and covered by fibrous slips and synovial membrane. The junction of the neck with the bone is marked by a large prominent body named the *trochanter major* (T), in which four surfaces may be recognised; an external lateral, for the insertion of the *glutæus medius*, and the motion of the tendon of the *glutæus maximus*; an internal with a pit, for the insertion of the tendon of the *pyriformis*, of the *gemelli*, and of the obturators; an anterior for the insertion of the tendon of the *glutæus minimus*; and a posterior for that of the *quadratus femoris*. At the union of the neck with the *diaphysis* below, and externally, is a conical eminence named the small *trochanter* (t), to which the united tendon of the *psoas magnus* and *iliacus internus* is fixed. The spaces between the trochanters before and behind are united by oblique rough lines, to which the femoral margin of the capsular ligament is attached, and the entire space within which is continuous with the articular cavity.

The lower or tibial extremity, which is large, is moulded into two rounded eminences named condyles (κονδυλοι) (1, 2; a, b); the one internal, deeper, and larger than the external, separated by an antero-posterior depression (*fossa intercondyloris*), and prominent and convex behind. Each condyle has an external and internal surface, while the articular one, which is incrusted by cartilage and synovial membrane, is shaped something like a horse-shoe, incurvated upwards in the middle before, and behind on each side, with elevated irregular margins for the attachment of the articular capsule. The intercondylar depression before receives the upper part of the knee-pan (*patella*), while in the intercondylar cavity behind are lodged the fimbriated margins of the synovial membrane, with the femoral ends of the cross ligaments, the anterior of which is inserted into the inner surface of the external condyle, and the posterior into that of the internal condyle. The outer or fibular surface of the external condyle presents an eminence for the attachment of the external lateral ligament, and a depression below for that of the *poplitæus*. The outer or tibial surface of the internal condyle has a prominent tubercle, to which are fixed the internal lateral ligament and the tendon of the *adductor magnus*. In a pit above each condyle the heads of the *gemellus* (*gastrocnemius externus*) are fixed.

The shaft or body, which approaches the cylindrical shape, is incurvated, with the convexity before, and the concavity behind (F, f). The anterior surface is uniformly round, and covered by the *cruræus*, which is fixed above to the interval between the trochanters. The posterior surface presents a rough elevated line, descending from the base of the large trochanter, meeting a similar line descending from the small trochanter, and inclosing a triangular rough space, forming about the middle third of the bone a rough elevated line (*linea aspera*) (l), which again is parted into two, less distinct; one termi-

Special Anatomy. nating on the external, the other very faint on the internal condyle. To the upper part of the external line, where it is most prominent, the tendon of the *glutæus maximus* is inserted; next is the short head of the *biceps;* and to the rest are fixed the fibres of the *vastus externus*. To the inner line the *pectinæus* and *adductor brevis* are inserted above, and the *vastus internus* is attached below; while the *adductor longus* and *magnus* are fixed to its whole length, unless at one point, where it is interrupted about three inches above the condyle by a smooth surface, on which the femoral artery passes under the tendon of the *adductor magnus*, to continue its course between the condyles, where it becomes the popliteal artery.

The *femur*, which is one of the most perfect examples of a long cylindrical bone, is compact in the *diaphysis*, with distinct medullary canal, and cancellated in the *epiphyses*. It is ossified in four portions; one for the *diaphysis* and neck, one for the two condyles, one for the head, and in general one for the *trochanter major*. The neck, which is short in early life, becomes long in adult age, and the body acquires its peculiar incurvation apparently from muscular action. In the female this incurvation is greater than in the male, and the neck forms a greater angle with the body.

The knee-pan. The knee-pan (*rotula, patella*) (P) is a short bone, shaped like a heart, with the apex downward, convex and fibrous before, where it is covered by tendinous matter; flat above, where the *rectus*, the two *vasti*, and the *cruræus*, are inserted; plane and concave behind, where it is covered by cartilage and synovial membrane, and separated into two unequal divisions by a middle ridge, forming the anterior wall of the knee-joint, and applied by its superior half over the anterior intercondylar *fossa*. The lower apex is rough for the attachment of the inferior ligament; and to the margins are fixed those of the fibro-tendinous capsular, by which it is connected to the *femur* and *tibia*.

The knee-pan, which has a peculiar cancellated structure, invested by a thin plate of compact bone, is to be regarded partly as a sesamoid bone for the insertion of the common tendon of the four extensors of the leg, partly as an appendage or *epiphysis* to the superior part of the *tibia*, performing to that bone the same function which the *olecranon* does to the *ulna*.

The shin-bone. The *tibia* is a prismatic-shaped long bone, situate at the inner and anterior region of the leg, with the femoral condyles above, the *astragalus* below, and the *fibula* on the external side.

The head, upper or femoral end, is large, and of an irregular oval shape. It presents two slightly concave elliptical cartilaginous surfaces, with the long diameter antero-posterior, separated by a rough vascular space, large before and narrow behind. Of these elliptical surfaces the external margin is most regular, and presents a crescentic or lunated mark for the attachment of the semilunar fibro-cartilages, which thus increase the concavity of the articular surfaces for the reception of the condyles. The inner or mesial margin of each is elevated into a curved peak, mutually separated by a depression. These eminences, which are jointly named the *spine* of the *tibia*, correspond in flexion and extension to the intercondylar *fossa*. Before is a triarcual surface, rough for the insertion of the anterior crucial ligament, and behind a notch for that of the posterior. The lateral circumference of the head, which is rough, and marked by vascular holes, presents before a triangular surface, the upper half of which corresponds to the inner surface of the knee-pan, and is contained within the cavity of the joint; while the lower angular portion is convex for the insertion of the inferior patellar ligament, or the last insertion of the tendon of the *rectus* and *vastus externus*. The sides, which are rounded and prominent, are named respectively the *external* and *internal tuberosities*, and give attachment to the external and internal lateral ligaments. To the back part of the internal also the tendon of the *semimembranosus* is fixed (d), while that of the external presents a cartilaginous facette for the articulation of the head of the *fibula* (c).

The lower or tarsal extremity, which is much smaller, is nearly quadrilateral, with a cartilaginous surface concave transversely, with elevated anterior and posterior borders, and the internal raised into a vertical eminence named the inner ankle (*malleolus internus*) (f), to the apex of which the internal lateral ligament is fixed. This cartilaginous surface, which receives the head of the *astragalus*, is surrounded by a furrow, very distinct before, in which ligamentous fibres are inserted; while the external margin, which is broader than the internal, presents between two prominences a trilateral hollow, in which the tarsal end of the *fibula* is lodged. The anterior surface is covered by the tendons of the *tibialis anticus* and *extensor proprius hallucis;* and the posterior, behind the internal ankle, is marked by a groove for the *tibialis posticus* and *flexor longus digitorum*, and another for the *flexor longus hallucis*.

The *body* or *diaphysis*, which is thick above, is prismatic, and presents three surfaces, bounded by the same number of lines. The first, which is anterior (*crista*), descends sharp and prominent from the anterior margin of the external tuberosity to the fore part of the internal ankle, and, though subcutaneous, gives attachment to the tibial aponeurosis and the *tibialis anticus*. To the external, which is sharp, and descends from the posterior margin of the same tuberosity to the anterior tubercle of the lower end, the interosseous ligament is fixed. To the internal, which is obtuse, and rather rounded, and descends from the posterior part of the internal tuberosity to that of the inner ankle, the *poplitæus* above, and the second or inner head of the *solæus*, with the *flexor longus digitorum*, are attached.

The surfaces bounded by these lines are *internal*, *external*, and *posterior*. The first, which is convex, gives insertion above to the *sartorius*, *gracilis*, and *semitendinosus*, and is elsewhere covered by integuments only. The external is concave above, where the *tibialis anticus* is fixed; convex below, where it is covered by the tendons of this muscle, and of the *extensor communis* and *proprius*. The posterior is crossed by an oblique line (T, 1, Plate XXV.) descending from the fibular articular surface to the internal line, and forming two spaces, the superior of which, triangular, is covered by the *poplitæus* inserted into the oblique line, while the lower, occupied by the *tibialis posticus* and *flexor longus*, presents also the medullary holes.

The *tibia*, compact in the *diaphysis*, with medullary canal, cancellated in the *epiphyses*, is ossified in three portions, one for the former part, and one for each of the latter.

The leg-bone. The *fibula*, which is the most slender bone of the skeleton of equal length, is situate at the outer side of the *tibia*, with its lower extremity anterior to the plane of the upper, articulated above with the latter bone only, below with the *tibia* and *astragalus* at once.

The head or tibial end, which is of an irregular cuboidal shape, presents above an oblique, trilateral, cartilaginous surface, articulated with that behind the external tibial tuberosity, by which also it is overhung. Before is a triangular surface, slightly convex, for part of the femoro-tibial ligament; behind, a tubercular surface for ligamentous insertions; and externally, between the two, is an extensive pentagonal surface for the insertion of the

Special Anatomy.

bicipital tendon, terminating above in an angular point, to which is fixed the peroneo-tibial ligament.

The lower or tarsal end consists of a pointed trilateral pyramid, the external surface of which, somewhat convex, is subcutaneous, and forms the external or fibular ankle (*malleolus externus*) (e). Within is a trapezoidal cartilaginous surface, which is articulated with the *astragalus;* and behind and below is a rough triangular surface, with a cavity for the insertion of the fibulo-tarsal ligament, while the external ligament is fixed to its angular tip. The posterior surface presents a groove, sometimes two, incrusted by fibro-cartilage for the motion of the *peronæi longus et brevis.*

The body is marked by several lines inclosing surfaces rather irregular in shape and extent. Among the former the following may be recognised:—An anterior, commencing about $2\frac{1}{2}$ inches below the head, distinct in the middle, where the *aponeurosis* common to the *extensor longus digitorum* and *peronæus tertius* before, and the *peronæus longus et brevis* behind, is attached, and bifurcating about $2\frac{1}{2}$ inches above the lower end into an anterior and posterior, terminating on the anterior and posterior margins respectively of the *malleolus externus,* inclosing a triangular space, which is covered by integuments only. The internal, descending from about an inch below the head to the anterior edge of the internal *malleolus,* coincides there with the anterior part of the anterior line. To this, above and in the middle, the *tibialis posticus* and *flexor proprius pollicis,* and below the interosseous ligament, are attached. The external or posterior descends from the posterior part of the head, obtuse, and winds round below to the posterior part of the tarsal end, giving attachment to an *aponeurosis* intermediate between the lateral *peronæi* without, and the *flexor proprius* and *solæus* behind. Between the external and the anterior is an oblique line, to which the interosseous ligament is fixed.

The external surface between the anterior and posterior lines, narrow above, convex and broad in the middle, and winding spirally round the axis of the bone, is covered by the *peronæus longus* and *brevis.* An anterior, plane, is covered by the *extensor longus* and *peronæus tertius.* The internal or tibial is divided by the oblique line into two; an anterior for the *extensor proprius,* and a posterior for the *tibialis posticus.* To the posterior surface above, which is convex, the *solæus* is attached; and in the middle and below the *flexor longus pollicis;* while, by the rough triangular surface below, the bone is articulated with the trilateral cavity of the *tibia.*

The *fibula,* which is ossified in three portions, partakes of the general characters of structure common to the long bones.

The tarsus. The *tarsus* consists of seven short irregular-shaped bones, the *astragalus,* the heel-bone (*calcaneum, os calcis*), the scaphoid, cuboid, and three cuneiform bones.

The first (*talus, astragalus*) has a convex cartilaginous surface above for articulation with the lower end of the *tibia,* continuous with a similar trilateral concave surface on the inside for articulating with the malleolar process, and with a smaller triarcual surface on the outside for the fibula; two cartilaginous surfaces, separated by a deep pit below, for articulating with the *calcaneum;* and an anterior eminence, with a convex cartilaginous surface, for articulating with the scaphoid bone before. The *calcaneum,* which is the largest, consists of the posterior tuberosity (*talus*) (c), for the insertion of the united tendons of the *gastrocnemius* and *solæus,* and that of the *plantaris;* two upper cartilaginous surfaces, separated by a ligamentous pit, for articulating with the *astragalus;* an anterior cartilaginous trilateral surface for the cuboid bone; an internal lateral sinuosity for the passage of the flexor tendons, that of the *tibialis posticus,* and the posterior tibial artery and nerves; and, lastly, an external lateral surface, covered by integuments and the tendons of the lateral *peronæi.*

The scaphoid bone is connected by its posterior concave surface with the anterior convex one of the *astragalus,* and presents before a cartilaginous surface with three facettes for the three cuneiform bones, and on the outside a small facette for the cuboid. On the inside is a prominent tuberosity for the attachment of the *tibialis posticus.* The cuboid bone, which constitutes the outer margin of the tarsus, and is articulated with the trilateral surface of the *calcaneum,* and by a minute facette with the scaphoid bone, is chiefly distinguished by an oblique or diagonal groove, for the tendon of the *peronæus longus.* The third and fourth metatarsal bones are articulated to its anterior surface.

The three cuneiform bones agree in having posterior cartilaginous surfaces for articulation with the scaphoid bone, and anterior ones for that with the first phalanx of the great toe, and the metatarsal bones of the second and third toes. The internal surface of the large cuneiform bone is convex, covered by integuments; the external or fibular cartilaginous, with two facettes for articulation with the second cuboid bone and the first metatarsal. Its lower surface is irregular for the insertion of the *tibialis anticus,* and part of the *tibialis posticus.* The second cuneiform bone, which is the smallest of the three, and the most like its name, is wedged between the scaphoid behind, the first and third on each side, and supports the first metatarsal bone before. The third, which also is not unlike its denomination, is wedged between the scaphoid behind, and the second cuneiform and the cuboid bone, and sustains the second metatarsal bone; while the third and fourth are articulated with the anterior surface of the cuboid.

The metatarsal bones. Of the metatarsal bones there are four; the first three similar to each other; the fourth, which sustains the phalanges of the small toe, distinguished by a large oblique angular head for the insertion of the tendon of the *peronæus brevis,* while that of the *peronæus tertius* is fixed above. Of the other three the heads are trilateral or wedge-shaped with the base upwards, with cartilaginous facettes on the sides for mutual articulation. The bodies are cylindrical, and, tapering, terminate in round heads flattened laterally. The dorsal or upper surface is covered by the extensor tendons, the *extensor brevis digitorum,* and the dorsal vessels and nerves derived from the anterior tibial artery and nerve. The surface of these bones is so constructed that it forms an arched or convex inclined plane, descending from the tibial to the fibular side of the foot. In the anterior or plantar surface, which is concave, are lodged the *abductor hallucis, abductor minimi digiti, flexor brevis,* the flexor tendons, the accessory flexor, the *lumbricales pedis, flexor brevis hallucis, abductor hallucis, flexor brevis minimi digiti, transversalis,* and the external and internal ranges of the *interossei.*

The phalanges. The *phalanges* of the toes, in number 15, bear a general resemblance to those of the fingers; but are considerably shorter, unless in the instance of the great toe. Like these also, they are disposed in three ranges,—metatarsal, middle, and unguinal.

The pelvic extremities in general. The hip-joint. The bones now described are united so as to admit of different degrees and forms of motion. The head of the *femur,* lodged in the *acetabulum,* is retained in that cavity not only by the capsular and round ligaments, but by the numerous strong muscles with which the hip-joint is surrounded. The length of the neck, which is peculiar to the human subject, throws the supporting column of

Special Anatomy.

the bone to a greater distance, not only from the pelvis, but from the mesial plane and centre of gravity; and this character, with the great proportional length of the bone, and the extent and direction of the pelvis, constitutes the most decisive argument in favour of the doctrine, that man must support himself in the erect position on the two pelvic extremities. In most quadrupeds the neck of the *femur* is short; the cylinder is shorter than the *tibia*, and not arched; and the *pelvis*, both by its vertical direction and peculiar dimensions, is calculated for the quadruped motion only. The femur admits of motion in every direction,—flexion, extension, adduction, abduction, circumduction, and rotation.

The knee-joint.

The *tibia*, with its appendage the knee-pan, is articulated to the condyles of the *femur* by means of an external and internal lateral ligament, strengthened by an anterior or patellar ligament, posterior fibres, and an anterior and posterior cross ligament, contained within the synovial membrane. The effect of this arrangement, with the anatomical configuration of the articular ends, is to allow cardinal opposition, or flexion and extension only. A small degree of rotation, nevertheless, may be effected.

The *fibula* is articulated to the *tibia* above by a genuine capsular joint, and below by fibrous matter, and connected at its internal side by a duplicature of periosteum forming the interosseous ligament. These connections admit of little motion, and the chief use of the *fibula* is to give attachment to several muscles which bend or evert the foot. The chief weight of the person, divided as it is between each lower extremity, is communicated from the *pelvis* to the *femur*, thence to the *tibia*, and finally to the *astragalus* and *calcaneum* behind, and the metatarsal bones before. The motion of opposition is confined to the former, which rolls backwards and forwards in the cavity formed by the lower extremity of the *tibia* and the *fibula* in the flexion and extension of the foot. In this, therefore, which forms the ankle-joint, all the motions of the foot as a whole are executed. It appears further to be susceptible of a slight degree of lateral rotation, so as to contribute to the eversion and inversion of the foot.

The ankle-joint.

The tarsal bones are mutually connected by cartilaginous surfaces, and secured by numerous fibrous bands, so as to admit of the gliding motion only. This motion is further between each individual articulation very limited, and its general amount is inconsiderable. The great use of the tarsal articulations is evidently stability and solidity as a base of support, not mobility.

The arches of the foot.

The bones of the foot form two distinct and separate arches,—an antero-posterior and a transverse. The first is constituted by the posterior part of the heel-bone behind and the metatarso-phalangeal articulations before; and its chief use is to distribute the weight of the extremity from the *astragalus*, which may be regarded as the centre, to the *os calcis* and extremities of the metatarsal bones on each side. In standing, for example, either on one foot or both, the weight of each extremity is distributed before to the metatarso-phalangeal joints, and behind to the tuberosity of the *os calcis*, while the anterior part of the latter bone and the whole second range of tarsal bones do not touch the ground. The second arch results first from the arrangement of the cuneiform bones with the scaphoid, and that of the cuboid with the *os calcis*; and next from the arrangement of the metatarsal bones. These arches, which are indistinct in early life, become conspicuous as the bones are completed, and acquire their complete developement in adult age. These arches are of great use in the alternate elevation of each half of the person in progression, in ascending an inclined plane or a series of steps, and especially in springing and leaping

The *phalanges* are articulated with the metatarsal bones and with each other, so as to admit of flexion and extension chiefly, with a very limited extent of abduction and adduction. The articulation of the great toe, also destitute of the power of opposition, abridges much its extent of motion. While these circumstances, with the great brevity of the phalanges, render the foot much less perfect than the hand as an organ of prehension, they extend its sphere of support, and enlarge its powers as a locomotive agent.

Parallel between the thoracic and pelvic extremities.

The pelvic and thoracic extremities present several points of resemblance which have been well traced by Soemmering. The head, neck, and tuberosities of the *humerus* resemble the head, neck, and trochanters of the *femur*; and if the lower end of the former bone is articulated both with the *ulna* and *radius*, while that of the latter is connected to the *tibia* only, there is still sufficient analogy between the lower ends of both bones. The *tibia* resembles the *ulna* above, with the knee-pan corresponding to the olecranon; but the lower extremity of the *tibia* is represented by that of the *radius*, in consequence of the extensive connection of the latter bone with the *carpus* for the purpose of pronation and supination. The navicular and lunar bones of the carpus are represented by the single *astragalus*,—an arrangement which appears to be allied in the latter case to the purpose of stability and solidity. The *calcaneum* may be regarded as an enlarged *os magnum*, fitted for the same purpose; and even in the shape and position of the scaphoid bone the same object may be recognised. This comparison, however, it is superfluous to pursue farther. The general conclusion is, that the thoracic extremities are intended to combine with strength great extent and precision of motion, while the purpose of the pelvic is stability, solidity, and strength.

SECT. II.—MYOLOGY; THE ANATOMY OF THE MUSCLES.

The muscles.

The muscles, with their appendages the fasciæ, tendons, and synovial sheaths, constitute the second division of the locomotive organs. By the term muscle, indeed, in Special Anatomy, is meant not only a mass of flesh adequate to effect motion, but an organ consisting of *fascia*, muscular flesh, and tendon, connected by the first and last substances to the parts, fixed or movable, to be approximated. While the middle portion is denominated belly (*venter*), the two extremities are most properly named *attachments*; though by others they have been termed respectively head or origin (*caput*, *origo*), and insertion (*insitio*) or termination (*finis*), according as the one or the other end has been imagined to be most fixed.

By the contraction of the middle portion or belly the two extremities are approximated; and according as the one is connected with a bone or soft part more movable than the other, that movable portion is approximated to the fixed. This, which is the general effect of muscular action, is well exemplified in the primary bones of the extremities, the muscles of which have their fixed end in general in the trunk, and their movable end attached to the bones of the extremities. Thus in the case of the *pectoralis major* (P), Plate XXVII., and *latissimus dorsi* (L, L), Plate XXVIII., the fixed ends are in the trunk, and the movable or insertions are in the *humerus*; and the effect of the contraction of the belly is to carry the *humerus* forward over the chest in the one case, and backward on the trunk in the other. This is easily applied to other muscles. as to those of the face.

The converse of this arrangement nevertheless may take place. The extremity, which in ordinary circumstances is the most movable, may be converted into the

fixed; while that which is fixed becomes movable. Thus, in the case of the two muscles already mentioned, the *humerus* may become the fixed point; and the effect will be to elevate and approximate the trunk to the part to which the extremity is fixed.

Though all the muscles are agents of motion, all are not of locomotion; and it is chiefly the muscles connected by both ends with the skeleton, and especially those of the extremities, which are entitled to this distinction. The muscles of the face are connected always by one end, often by both, with the skin, and hence are cutaneous muscles. Those of the lower jaw and pharynx are organs of motion simply to move the parts with which they are connected in the acts of mastication and deglutition. Those of the larynx are of two orders, the *common* or *extrinsic*, connected to some of the bones of the head and chest; and the *proper* or *intrinsic*, pertaining to the laryngeal cartilages only. Those of the eye and ear, external and internal, are equally unconnected with the locomotive faculty.

These circumstances have induced several authors, especially the ancient anatomists, and among the moderns Winslow, to arrange the muscles according to the parts which they move. By others, however, especially Douglas and Albinus, they have been classified according to the regions which they occupy; and this method, which is certainly more strictly anatomical, has been more or less adopted by Innes, Sabatier, Bichat, and Boyer. To the first method the principal objection is, that the same muscle may pertain to different classes of organs, and may effect different purposes in each; while of the second it must be admitted, that it communicates no information regarding the remarkable part which the muscles perform in the complicated processes of the animal machine. This consideration it was which induced Albinus, after a minute description of the situation, connections, and separate actions of each muscle of the human body, to construct a table representing the various classes into which they may be divided, according to the parts on which they act; for the same reason, doubtless, Soemmering arranged them according to the organs to which they belong; and for the same reason Portal, after a description equally minute with that of Albinus, gives a second account of the muscles as they are observed to act in the living body.

In the following tabular view, modified from that given by Albinus in the fourth book of his *Historia Musculorum*, the muscles are arranged according to their regions.

Muscles of the Head, Neck, and Vertebral Column.

Latissimus colli. (Π.)	Rectus capitis posticus major.
Sterno-mastoideus. (σr.)	Rectus capitis posticus minor.
Splenius capitis. (s.)	Obliquus capitis superior.
Splenius cervicis.	Obliquus capitis inferior.
Biventer cervicis.	Rectus lateralis.
Complexus. (c. c.)	Rectus capitis anticus major.
Trachelo-mastoideus.	Rectus capitis anticus minor.
Transversus cervicis.	Longus colli. (l.)
Cervicis descendens.	Scalenus anticus.
{ Longissimus dorsi. (LO.)	——— medius. (sc.)
{ Sacro-lumbalis, and	——— posticus.
{ Spinalis dorsi. (s.)	Intertransversi colli priores.
Spinalis cervicis.	Intertransversi colli posteriores.
Semi-spinalis dorsi.	Intertransversi dorsi.
Multifidus spinæ.	Intertransversi lumborum.
{ Interspinales cervicis.	
{ ——— dorsi.	
{ ——— lumborum.	

Muscles of the Chest.

Sterno-costalis.	Levatores costarum breviores.
Serratus posticus superior.	Intercostales externi
Serratus posticus inferior.	Intercostales interni.
Levatores costarum longiores.	

Common to the Chest and Abdomen.

Septum transversum, *sive* Diaphragma.

Muscles of the Abdomen and Loins.

Obliquus externus. (o.)	Quadratus lumborum.
Obliquus internus.	Psoas parvus.
Rectus. (R. R.)	Psoas magnus.
Pyramidalis.	Iliacus internus.
Transversus. (T.)	

Muscles of the Thoracic Extremities.

The Shoulder.

1st Order.	Supraspinatus. (s. s.)
Subclavius.	Infraspinatus. (i. s.)
2d Order.	Teres minor. (t.)
Serratus magnus. (s.)	Teres major. (T.)
Cucullaris. (c. c.)	Subscapularis.
Rhomboideus major. (P.)	*4th Order.*
Rhomboideus minor.	Latissimus dorsi. (L.)
Levator scapulæ. (L. s.)	Pectoralis major. (P.)
3d Order.	Pectoralis minor. (P.)
Deltoides. Δ.	

Muscles of the Arm.

Coraco-brachialis.	Triceps brachii. (Tr.)
Biceps brachii. (B. b.)	Anconeus.
Brachialis internus. (Br.)	

Muscles of the Fore-Arm and Wrist.

Supinator longus. (s.)	Ulnaris internus.
Radialis externus longior. (F.)	Radialis internus.
	Pronator teres. (Pr.)
——— brevior.	Pronator quadratus.
Ulnaris externus.	Supinator brevis.

Muscles of the Hand and Fingers.

Extensor communis.	Abductor brevis pollicis
Extensor proprius auricularis.	Opponens pollicis.
Abductor longus pollicis.	Flexor brevis pollicis.
Extensor minor pollicis.	Adductor pollicis.
Extensor major pollicis.	Palmaris brevis.
Indicator.	Abductor digiti minimi.
Palmaris longus. (p.)	Flexor parvus digiti minimi.
Sublimis. (F. s.)	Adductor ossis metacarpi digiti minimi.
Profundus. (F.)	Interossei interni.
Flexor longus pollicis.	Interossei externi.
Extensor brevis indicis.	Abductor indicis.
Lumbricales.	

Muscles of the Pelvic Extremities.

The Hip.

Glutæus magnus. (GL.)	Obturator internus. (ob.)
Glutæus medius. (G. I.)	Obturator externus.
Glutæus minor.	Quadratus femoris. (q.)
Pyriformis.	*Psoas magnus.*
Gemini. (g. g.)	*Iliacus internus.*

Muscles of the Thigh.

Biceps cruris. (B.)	Vastus externus. (v.)
Semitendinosus. (s. T.)	Vastus internus. (v.)
Semimembranosus. (s. M.)	Cruralis.
Tensor vaginæ femoris. (T.)	Pectinæus.
Sartorius. (s.)	Adductor longus. a.
Gracilis. (g.)	Adductor brevis.
Rectus.	Adductor magnus. a.

Special Anatomy. The muscles.

Muscles of the Leg and Tarsus.

Gemellus.	Peronæus longus. (p.) Its tendon in the groove of the cuboid bone.
Plantaris.	Peronæus brevis.
Solæus.	Extensor l. digitorum pedis.
Poplitæus.	Peronæus tertius.
Flexor longus digitorum pedis.	Tibialis anticus.
Flexor longus hallucis.	Extensor proprius hallucis.
Tibialis posticus.	

Muscles of the Foot and Toes.

Extensor brevis digitorum pedis.	Abductor digiti minimi pedis.
Flexor brevis digitorum pedis.	Flexor brevis digiti minimi pedis. (f.)
Abductor hallucis.	Transversus pedis. (tr.)
Flexor brevis hallucis. (F. 4.)	Lumbricales pedis.
Adductor hallucis. (a. d.)	Interossei interni pedis.
	Interossei externi pedis.

Muscles of the Lower Jaw.

Biventer maxillæ.	Pterygoideus externus.
Masseter.	Pterygoideus internus.
Temporalis.	

Muscles common to the Hyoid Bone, Tongue, and Larynx.

Omohyoideus.	Styloglossus.
Sternohyoideus.	Mylohyoideus.
Sternothyroideus.	Geniohyoideus.
Hyothyroideus.	Hyoglossus.
Thyroideus.	Genioglossus.
Stylohyoideus.	Lingualis.

Muscles of the Palate and Pharynx.

Levator palati.	Palato-pharyngeus.
Azygos uvulæ.	Stylo-pharyngeus.
Circumflexus palati.	Salpingo-pharyngeus.
Constrictor isthmi faucium.	Constrictores pharyngis.

Proper Muscles of the Larynx.

Crico-thyroideus.	Arytænoideus transversus.
Crico-arytænoideus posticus.	Thyro-arytænoidei.
Crico-arytænoideus lateralis.	Thyro-epiglottici.
Arytænoideus obliquus.	

Muscle of the Scalp.

Epicranius. (E, bE, bE, E.)

Muscles common to the Face and Eye.

Orbicularis palpebrarum. (o.o.)	Levator palpebræ superioris.
Corrugator supercilii.	

Muscles of the Nose.

Compressor narium. (c.)	Nasalis labii superioris. (N.)
Levator labii superioris alæque nasi. (L.)	Depressor alæ nasi. (d.)

Muscles of the Lips.

Levator labii superioris.	Depressor labii inferioris.
Zygomaticus minor. (z.)	Buccinator. (t.)
Zygomaticus major. (Z.)	Orbicularis oris. (o. o.)
Levator anguli oris.	Anomalus maxillæ superioris
Depressor anguli oris.	Levator menti.

Muscles common to the Ear and Scalp.

Attollens auriculam.	Minor helicis.
Prior auriculæ.	Tragicus.
Retrahens auriculam.	Antitragicus.
Major helicis.	Transversus auriculæ.

Proper Muscles of the Eye.

Attollens. (A.) Plate XXXIII. fig. 6.	Adductor. Ad.
Depressor. (D.)	Obliquus superior. Tr.
Abductor. (Ab.)	Obliquus inferior.

Proper Muscles of the Ear.

Laxator tympani major.	Tensor tympani.
Laxator tympani minor.	Stapedius.

Muscles of the Anus and Perinæum.

Transversus perinæi.	Levator ani.
Transversus perinæi alter.	Coccygeus.
Sphincter ani externus.	Curvator coccygis.
Sphincter ani internus.	

Muscles proper to the Male Generative Organs.

Cremaster.	Bulbo-cavernosus.
Ischio-cavernosus.	Compressor prostatæ.

Muscles proper to the Female Generative Organs.

Ischio-clitoridæus.	Depressor urethræ.
Constrictor vulvæ.	

The limits assigned to the present treatise preclude particular details on the situation and relations of this numerous list of muscular organs. Any description sufficiently minute for the purpose of explaining the situation, attachments, relations, and actions of the muscles of the different regions, would be tedious in the extreme, and would not be intelligible without dissection; and no description according to their actions only would be intelligible, without a previous account of their anatomical relations. For these reasons it seems most expedient to direct the attention of the reader to a few general circumstances only. For descriptive details the reader will study with advantage the third book of the elaborate and accurate *Historia Musculorum* of Albinus, or the more recent treatise of Sandifort. The descriptions of Innes are clear, short, and sufficiently minute; and a good account of the muscles, as they appear on exposition, is given in the *London Dissector*. Of systematic treatises, the second volumes of those of Soemmering, Portal, and Bichat are the best.

This section, therefore, we shall conclude with such a general view of the muscles as agents in the attitudes and motions of the trunk and extremities, as, with the occasional remarks on their situation and connections in describing the bones, may be easily intelligible. It is further proper to advert briefly to those of the flexor muscles of the fingers, partly with the view of illustrating the general effects of muscular action, partly to show the mechanism by which the hand and fingers are enabled to execute such a variety of nice and delicate motions.

Muscles of the trunk.

The muscles of the trunk are employed not only as agents of motion and sustentation, but as the protecting walls of the large cavities. Thus the external and internal ranges of intercostals, the two pectorals, and the *serratus magnus*, operate not only in moving the ribs and shoulder respectively, but in contributing to complete the walls of the thorax, and to protect the internal organs. The diaphragm is not only an agent in enlarging the chest downwards, but constitutes an essential partition between the thoracic and abdominal viscera, prevents the lungs and heart from descending into the abdomen, and the stomach and bowels from being thrust upwards into the chest. These characters are still more conspicuously displayed in the *recti abdominis*, *obliqui externi et interni*, and *trans-*

Special Anatomy.

The muscles.

versi abdominis, which operate a little in drawing the chest downwards and compressing it before and on the sides, but act much more powerfully as retaining and supporting walls of the abdominal viscera, counteracting by the inward and upward action the downward impulse of the diaphragm. In this manner the abdominal *viscera*, placed between two opposing but equally balanced powers, are retained in the cavity, and prevented from being protruded upwards or downwards, while they are subjected to the alternate motions of inspiration and expiration.

The muscles of the trunk are employed in retaining that part of the skeleton in the erect attitude, in balancing it properly on the pelvic extremities, in occasionally inflecting and extending it, in bending it to one side, or in producing rotation. Those of the spine and back are particularly the agents of the erect attitude, and of extension; and those of the anterior region are employed in inflecting the person.

Muscles of the thoracic extremities.

The muscles of the superior extremities taken together are the agents of numerous varied motions. Though the principal object of the thoracic extremities is *prehension*, or embracing any object or objects firmly either by one or both hands, this may be modified in various ways, so as to give rise to prepulsion, traction, and constriction; while diduction and circumduction are the result of the combinations of the simple movements,—abduction, adduction, flexion, and extension.

Prepulsion.

Prepulsion may be either instantaneous or continued. The first takes place in the act of inflicting a blow or repelling an object. All the flexors are previously put in action to shorten the member, which is then at once forcibly extended, and communicates a violent shock to the part of the object to which its extremity is applied. Of this motion, in which the extension takes place in the scapulo-humeral and humero-cubital articulations, the deltoid and *brachialis externus*, or third head of the *triceps*, are the chief agents. The wrist and fingers are almost passive. But an analogous motion is executed by the latter in giving a fillip. In continuous prepulsion, for instance, or the act of impelling an object, the mechanism is of two kinds. In the first case, the member being previously extended and supported on the object, the individual inclines the trunk, and avails himself of its weight; while the member, remaining passive, becomes a lever moved by gravity. In the second case, the continued action of the extensors retaining the member forcibly extended, impels the object without interruption. When, for example, a man pushes a wheel-carriage before him, the superior extremities are extended and communicate motion to the carriage, while the trunk approaching it immediately, the extremities are again inflected, and so forth successively. In most instances this twofold mechanism is combined. When in prepulsion the body impelled is fixed, the impulse is thrown back on the person of the prepelling agent. Examples of this effect of prepulsion are observed in the act of rising from a seat by the occasional use of the thoracic extremities, and in pushing a vessel from the shore by means of an oar or pole.

Traction.

Traction, which consists in a general action of the flexors of the thoracic extremities, is directly the reverse of prepulsion. Its effect is to diminish the space between the agent and the object drawn, which takes place by shortening the member; while in prepulsion this space is enlarged by elongating or extending the member. In the case of a very great effort, for instance that of detaching a piece of wood strongly fixed in a wall, the action of the flexors is aided by the weight of the trunk, which is instinctively inclined in the opposite direction; and if the body drawn yields at once, a fall is often the result, because in this inclination the centre of gravity is subverted. In another form of traction, in which the body grasped does not yield, and when the action takes place upwards, the effect is to elevate the person of the agent by the flexors of the superior, and even occasionally of the inferior extremities. Familiar examples of this are afforded in the act of climbing walls, trees, and occasionally rocks, in ascending the rigging of a ship, and still more forcibly in the manner in which the active seaman ascends a single rope.

Constriction.

Constriction consists in the forcible and continued inflection either of a single hand or of the whole of both members. In the first case the agents are the superficial and deep flexors, and the flexors of the thumb and little finger; and in the second, with the action of these muscles, that of the *biceps*, *brachialis internus*, and *coraco-brachialis* is combined. This motion can neither be so sudden as that of prepulsion, nor, like it, can it be aided by the weight of the person.

Diduction.

Diduction, which consists in the forcible separation of the upper extremities from each other, as in swimming, is effected partly by the *latissimus dorsi* and *teres major*, partly by the posterior *fasciculi* of the deltoid moving the whole extremity in the scapulo-humeral articulation.

Circumduction.

Circumduction, which also is exclusively confined to the scapulo-humeral articulation, is effected principally by the deltoid, large pectoral, *latissimus dorsi*, *teres major*, &c.; while rotation is performed by the *supraspinatus*, *infraspinatus*, *teres minor*, *subscapularis*, &c.

Gesture.

Besides these general classes of motion executed by the thoracic extremities, to them also belongs the power of assuming many of those attitudes and all the varieties of gesture which man employs for the purpose either of expressing his feelings or giving significance and animation to the language which he adopts for that purpose. How much these gestures, when well chosen and properly introduced, aid both the expression of the countenance and the language of the lips, is well known to the public speaker and the dramatic performer.

Motions of hand and fingers.

Besides the ordinary flexors of the wrist (*radialis externus et internus*, *ulnaris internus*), there are two common flexors of the fingers, one superficial (*sublimis*), the other deep-seated (*profundus*); the thumb has a long and short flexor, and the little finger has a short flexor. The flexor muscles, therefore, may be distinguished into four orders; those common to the wrist and hand, those common to the hand and fingers, those proper to the fingers, and those proper only to some of the fingers. Though the *radialis internus* and *ulnaris internus* chiefly bend the wrist and hand, yet both the superficial and deep flexors, by passing beneath the annular ligament, co-operate in the same motion, and necessarily bend the hand previous to their final action on the digital phalanges. In this they are considerably aided by the action of the *palmaris longus* and the *palmaris brevis*, which render the palmar aponeurosis tense, and enable it to afford the necessary resistance to the subjacent flexor tendons.

The superficial flexor, the tendons of which are inserted into the anterior and citerior part of the second row of phalanges, has the effect of bending that part of the fingers, and further, by being bound down by a ligamentous sheath to the first phalanx, inflects them at the same time into the palm. The slits in each tendon allow those of the deep flexor to pass forward on the median line of each phalanx, to be inserted in the unguinal phalanges, and thereby to operate most directly and perfectly in inflecting them on the palm; and, by being confined also in the same sheath by strong ligamentous bands, aid in inflecting the second and first range of phalanges. (Plate XXVIII. fig. 2 and 3.)

Special Anatomy.

Minute flexion and extension.

These actions are further facilitated and modified by another class of muscles. The *lumbricales*, which, situate in the palm, are attached above to the tendons of the *flexor profundus*, and inserted sometimes into the extensor tendons, sometimes into the lateral regions of the phalanges, may either concur with the *profundus* in bending the first phalanges, or they may adduct or abduct the fingers, according to the separate or conjunct motion; and hence are of the utmost importance in all nice and minute motions of the fingers. Without the *lumbricales*, which are peculiar to man, it would be impossible for the human fingers to execute those minute and rapid movements which are necessary in performing on musical instruments; and the great advantage which one individual possesses over another in what is denominated *execution*, consists chiefly in the perfect use of these little muscles. In playing on the piano-forte especially, the *lumbricales* are of the most essential service; and though the superficial flexor enables a lady to strike the keys, the former must be employed in the more minute and delicate motions requisite in the transition through numerous chords.

In this action the *internodii* at the same time appear to be auxiliary; and their connections are calculated to modify the action of the flexors.

Opposition of thumb and fingers.

Another peculiarity in the human hand consists in the four muscles with which the thumb is provided, and the two connected with the little finger. By means of its short abductor, short flexor, and adductor, the thumb may be separated, inflected, and approximated to the hand quite independently of the fingers, and with the utmost precision. But from the *opponens* it derives the remarkable property of being accurately and precisely applied to the tip of any one of the fingers, and thus made to grasp minute objects, which could not without this be effected. From this muscle, in short, the human hand derives its power of appliance to all the arts requiring nice manual operation. Without the *opponens* there is no penmanship, no painting, no drawing, no tracing, no needlework, no engraving; in short, none of those operations requiring the obedience of the hand to the conceptions of the mind and the guidance of the eye.

General movements of the pelvic extremities.

The movements of the lower extremities are less distinguished for precision and delicacy than those of the superior; and though the foot has both *lumbricales* and *interossei*, the brevity of the phalanges compared with the length of the metatarsal bones, and the close connection of the toes, form insurmountable impediments to the rapidity and nicety of motion which is observed in the inflections of the fingers. The circumstance, however, which places the foot at an immeasurable distance behind the hand as an organ of prehension, is the want of the *opponens*. Void of this, the human foot is little more than the foot of the quadruped, constituting chiefly a base of support, and susceptible of such motions only as are requisite to progression. It is expedient, therefore, to consider shortly the agents by which these functions are performed.

Station on both legs.

Station, or that attitude in which man supports himself in the erect position on a horizontal plane, is effected by the foot being planted firmly on the ground by means of the *gemellus, solæus, tibialis anticus, peronæus longus et brevis, flexor longus communis digitorum pedis, flexor hallucis proprius, flexor hallucis brevis, flexor brevis digiti minimi et digiti medii*, the *lumbricales*, and *interossei*. At the same time the leg is fixed to the ground by numerous muscles,—before by the extensors of the great toe and toes generally, by the *peronæus tertius*, partly by the *tibialis anticus*; externally by the *peronæi longus et brevis*; within by the *tibialis anticus* and *posticus*; and behind by the *gemellus, solæus, semitendinosus*, and long flexors of the toes. The knee is at the same time stretched by the four extensors, aided by the *tensor vaginæ femoris*.

Equipoise.

The equilibrium of the trunk and pelvis on the heads of the thigh-bones is maintained by several powerful muscles, connecting the former to the latter. Before, for instance, this action is performed by the *sartorius, rectus*, the two *psoæ*, and the *iliacus internus*; behind by the *biceps, semitendinosus*, and *semimembranosus*; without by the *glutæus* and *tensor vaginæ femoris*; and within by the *pectinæus*, the adductors, and the *gracilis*. By these muscles the pelvis is impelled on the axis of the two *femora* only, and is prevented from inclining in any other direction. To maintain the trunk above the pelvis in the same steady position, numerous other muscles concur. Behind are the various extensors of the vertebral column and trunk, the *longissimus dorsi* and *sacro-lumbalis* on each side, the *cervicis descendens, splenius* and *biventer cervicis*; the *transversi cervicis*, and *spinalis cervicis et dorsi*; the *semispinalis, multifidus*, and *interspinales* on each side. Before are the sterno-mastoid, the great and small anterior *recti*, the *longi colli*, and anterior *scaleni*; and on each side are the trachelo-mastoid, the lateral *scaleni*, the *intertransversi*, and the lateral *recti*. In this enumeration it is manifest that the muscles of the posterior surface of the trunk and spine are at once more numerous and more powerful than those on the anterior,—an arrangement which is rendered necessary to counteract the effect of the weight of the thoracic and abdominal viscera on the anterior side of the vertebral column, which is thus rendered liable to anterior incurvation, and which becomes so in old age, notwithstanding the agents now mentioned.

This circumstance is further illustrated in the number and size of the muscles by which the head is retained in the erect position, and prevented from inclining forwards. These are the *cucullares*, the *splenii capitis, biventres cervicis*, and posterior *recti* on each side—all powerful, and several of them large.

Station on both pelvic extremities, therefore, requires the co-operation of a very considerable number of powerful muscles; and it is a mistake to imagine, as some authors appear to do, that a small degree of muscular energy is requisite for this purpose, and that the skeleton is the chief means of maintaining the erect position. Without the skeleton, as points of support, the muscles cannot act; but without the muscles the bones are passive brute matter.

Station on one leg.

In station on one extremity only, a different and certainly a less degree of muscular action is requisite. All the external muscles of the fixed member are at first strongly contracted, to prevent it from gliding inwards, in which direction the trunk, not supported by the opposite limb, tends to impel it. Proceeding from below upwards, we find the lateral *peronæi*, the *vastus externus*, and even the *rectus*, draw the limb outwards; while the *tensor vaginæ femoris*, the *glutæus medius* and *minor*, carry the pelvis, and with it the trunk, in the same lateral direction. In this case the weight of the person is employed in antagonizing the muscles of the side thrown into action; and the person is balanced between these two forces.

Elevation on the tip of the foot is effected chiefly by the action of the muscles, which extend the *phalanges* on the metatarsal bones, viz. the *tibialis anticus, extensor hallucis, extensor longus digitorum*, and even the *extensor brevis*; all of which must fix the leg before, and the tarsal and metatarsal part of the foot on its phalangeal region, before the latter can be employed to elevate the person These extensors, therefore, perform in the tip-toe attitude the duty which the *gastrocnemius* and *solæus* execute behind in ordinary station; and the smaller power

Special Anatomy.

of the former readily explains the difficulty of maintaining this attitude for a long time.

Progression.

Progression or gait (*incessus*) consists in the anterior propulsion of the person by the alternate propulsion of each pelvic extremity. In this, therefore, not only are the muscles necessary to maintain the erect position put in action, but those which bend the lower extremity on the trunk operate on one side, while the extensors of the other maintain that extremity for the instant fixed. Progression consists of a series of steps (*passus*); and each step consists in the antero-posterior separation of the pelvic extremities by the propulsion of one, while the other remains fixed. Supposing the left foot to be the fixed one, the right foot is elevated, and the leg is propelled by the contraction of the *gemellus, solæus, semitendinosus, tibialis anticus et posticus;* while at the same time the extensors of the knee raise the leg, and the *psoas, iliacus, pectinæus, triceps adductor, sartorius* and *gracilis,* with the *tensor vaginæ femoris,* raise and stretch the whole limb. When this is accomplished, the right foot, with the knee extended, the elevating muscles being relaxed, and the trunk, are inclined forwards, and the foot is planted at some distance before the left.

In this motion, however, in which the trunk is carried forward by the *recti* and *obliqui abdominis,* and downward by the *psoæ* and *iliaci interni,* and the leg by the long flexor and the anterior *peronæus,* a fall would be the immediate result, unless the knee, to preserve equilibrium, were somewhat bent, and the other foot at the same time began to assume the same action. While the toes, therefore, are forcibly impelled by their flexors to the ground, the two *gastrocnemii,* the anterior and posterior *tibiales,* and the *peronæi,* elevate the foot with the sole backward, and bend the knee, and the *psoas* and *iliacus* raise and extend the whole member.

Running.

Running differs from progression, not only in velocity, but in the mode of its accomplishment. Not only are the pelvic extremities more inflected and moved than in mere walking, but they remain inflected. Thus, while the trunk is inclined forward on the pelvic extremities by the *recti cruris,* the *psoæ* and *iliaci,* the two latter with the *pectinæus longus,* the *adductor longus* and *brevis,* and the *tensor,* are employed to inflect the thigh, the *semitendinosus, semimembranosus,* and *biceps* to inflect the leg, and the anterior *tibialis,* great and small extensors of the toes, and extensor of the great toe, are employed to bend the foot and the phalanges on the metatarsal bones. The last action is essential to running, which is always most perfect on the tip of the foot. In this movement also the centre of gravity is constantly undergoing change, and is not only carried forward, but makes a sort of undulating motion on each side, and above and below the plane of motion. This is the effect of the pectoral extremities being employed to balance the person.

Leaping.

In leaping, the pelvic extremities are much inflected, and the sole of the foot rendered tense, by the *gastrocnemius, solæus, tibiales,* and *peronæi,* while the extensors are employed to raise the phalangeal part of the foot; when the person is forcibly impelled forward by the *gastrocnemius, solæus,* the leg suddenly contracting on the *cruræus* in the thigh, and the *glutæus, semitendinosus, semimembranosus,* and *biceps* in the pelvis.

Dancing.

In dancing, the muscles are made to co-operate in producing a number of complicated motions. In most of the motions composing the dances practised in ordinary society, while the muscles of the pectoral extremities are employed in balancing the person, and those of the trunk in maintaining it in the erect attitude, the flexors and extensors are employed to diduct, inflect, or extend; to cross the extremities with more or less rapidity; and, while the extensors and *tibialis anticus* elevate the person on tip-toe, the lateral *peronæi* are employed to evert the foot and point the toes.

CHAP. II.—THE ORGANS OF SENSATION.

The organs of sensation may be distinguished into two orders, according as their province is to recognise general or peculiar affections and qualities in external objects. Thus, while it is the purpose of touch to recognise the consistency, shape, and resistance of bodies, it communicates no information regarding their colour, smell, or taste, or the effects which their collision produces in the vibrations of the atmosphere. With these affections of the material world man becomes acquainted by means of organs of a peculiar construction, and adapted to receive the impressions occasioned by these qualities. These organs are, for smell, the nostrils and their appendages; for colour and the general purposes of sight, the eye; for taste, the palate and mouth; and for sound, the ear. For the purposes of common sensation the skin is the agent; but on the structure of this membrane it is unnecessary to add any thing to what has been already said in the General Anatomy, unless that in certain regions, for instance the tips of the fingers, the erectile arrangement of the capillaries, with a minute distribution of nerves, and great thinness of cuticle, communicates the delicacy necessary to the refined purposes of tact.

SECT. I.—THE ORGAN OF SMELL; THE NASAL CAVITIES.

The organ of smell consists of an external part for receiving and transmitting substances capable of producing the sensation of smell; and an internal part, in which this sensation takes place.

The nose (*nasus*), which constitutes the external part, is a pyramidal eminence, bounded above by the forehead, below by the upper lip, and on the sides by the orbits and cheeks. It has two anterior-inferior oval-shaped lateral openings named the nostrils (*nares*), separated by a partition. It consists above of the nasal bones and the nasal processes of the superior maxillary bones, covered by periosteum, cellular tissue, part of the *compressor narium,* and skin. Below, it consists of membranous fibro-cartilages, attached to the nasal bone and superior maxillary above and behind, and supported by a middle cartilage (*septum narium*), which rests on the fissure of the *vomer* below, and is fixed to the vertical plate of the ethmoid bone above, and to which is attached a slip of fibro-cartilage before, named *columna nasi.* The lateral fibro-cartilages, which are occasionally named wings (*alæ nasi, pinnæ nasi*), covered by cellular tissue, muscles, and skin, liberally supplied by blood-vessels and sebaceous follicles, are moved by the *levator, compressor,* and two depressors. These parts, with the middle *septum* and *columna,* are lined by a form of mucous membrane named the pituitary or Schneiderian. The nose.

To what was already said of the nasal cavities under the head of Osteology it is superfluous to add any thing, unless what relates to the lining membrane, the distribution of which is exactly according to the extent of the bony walls of these cavities and their subdivisions.

This membrane consists of two layers; a *fibrous,* which is the periosteum or perichondrium of the nasal cavities; and a *mucous,* resembling the other forms of this tissue. It is soft, spongy, red, and more or less vascular, with an attached and a free surface, the latter secreting the thin mucus necessary to preserve the membrane in a proper state for receiving odorous impressions. In this mem- Narine membrane.

Special Anatomy.

brane mucous glands are indistinct; but we recognise minute orifices or pores, which may be the follicular cavities on a small scale, or the orifices into which the mucous fluid is poured after secretion by the arteries.

This mucous membrane is supplied from the internal maxillary artery with blood-vessels, which are at once abundant and superficial. These anastomose with the infra-orbital and ethmoidal branches of the ophthalmic artery and some others of the internal carotid. On these circumstances depends the frequency of hemorrhages from this membrane in early life, while the capillary system is energetically employed in the enlargement of the cranio-facial region; and in advanced life, when venous *plethora* is most conspicuously evident in the vessels of the head.

The nerves which supply the nasal cavities are the first or olfacient nerves principally, the internal nasal of the ophthalmic, and several branches derived from the spheno-palatine ganglion, the frontal, the great palatine, and the vidian. The distribution of these nerves has been beautifully represented by Scarpa (*Annot. Acad.*), from whom fig. 1 and 2 of Plate XXXIII. are imitated.

SECT. II.—THE ORGAN OF VISION; THE EYES.

The eyes, placed in the orbits, are distinguished into the globes of the eyes, and their appendages.

The globe or ball of the eye, situate at the base of the orbit, has a spheroidal shape, with the antero-posterior diameter longest, and varying in the adult from 10 to 11 lines. The direction of the eye differs from that of the orbit, the axis of which is oblique and convergent behind, while that of the two eyes is parallel.

The eye-ball (*bulbus oculi*) consists of several membranes, containing fluid or semifluid substances, denominated humours. The external and strongest is the sclerotic, with the *cornea* enchased in its anterior aperture; next is the choroid and retina; and the iris, a circular membrane, with an annular aperture, is placed transversely across, dividing the cavity into anterior and posterior chambers. The humours are the vitreous, the crystalline lens, and the aqueous humour.

The sclerotic.

The sclerotic, sometimes named *cornea opaca*, in contra-distinction to the clear cornea, is shaped like a spherical shell, truncated before, and is estimated to occupy about four fifths of the globe. Its exterior surface is covered by the adipose matter of the orbit behind, and by the tendons of the muscles of the eye and the ophthalmic *conjunctiva* before. Its inner concave surface is lined by the choroid coat. In its anterior opening, which is about six or seven lines diameter, the cornea is enchased by imbrication of the sclerotic; and in a posterior opening about one and a half line in diameter, the ophthalmic end of the optic nerve is fixed. It is fibrous in structure, becoming translucent when immersed in oil of turpentine. Its vessels are generally colourless, and it appears void of nerves.

The cornea.

The *cornea*, often named the clear or transparent *cornea* (*cornea lucida*), to distinguish it from the opaque cornea or sclerotic, which was supposed by the old anatomists to be of the same nature, is a segment of a smaller sphere than that of the sclerotic, attached to its anterior aperture, and occupying the anterior fifth of the eyeball. Before it is covered by a thin pellicle continued from the *conjunctiva*, behind by the anterior part of the membrane of the aqueous humour; and its circumference is inseparably enchased within that of the anterior aperture of the sclerotic. The cornea consists of several concentric layers of transparent homogeneous matter, void of vessels or nerves, closely united, but separating and becoming opaque after death.

The choroid coat.

The choroid coat (*tunica choroides*) lines the inner surface of the sclerotic, to which it adheres loosely, except at the insertion of the optic nerve, where it has a posterior opening, yet may be easily detached. The margin of its anterior opening, which is large, adheres to the ciliary circle and processes, and appears to be continuous with the iris. The outer surface is covered by a brownish-black viscid matter, which partly adheres to the inner surface of the sclerotic. The inner surface, over which the *retina* is extended without adhesion, is covered by the same brownish-black matter; but of this the retina receives none, as the sclerotic. The choroid is a thin membrane, of a grayish colour when deprived of its brown pigment, translucent, homogeneous, and, so far as observation goes, void of fibres, but liberally supplied by minute blood-vessels, partly from the long, chiefly from the posterior ciliaries, which, dividing on its outer surface into numerous ramifications, mutually approximate, and anastomosing, form a network of quadrilateral and trapezoidal meshes. The *tunica Ruyschiana* is imaginary, unless this arrangement of capillary vessels be such.

Pigmentum nigrum.

From these vessels is derived the brownish-black matter (*pigmentum nigrum*) with which the retinal surface of the choroid is covered. Its appearance on the convex or sclerotic surface is the effect of cadaveric transudation. The nature of this colouring matter is imperfectly known. When first secreted it is brown, but becomes black successively as it continues. It is not affected by the action of light or caloric, and undergoes no change from the operation of the mineral acids, *aqua potassæ*, ammonia, and alcohol. It appears to consist chiefly of carbonaceous matter. Menghini asserts that he has obtained from it minute particles of iron attracted by the magnet.

Ciliary circle.

The anterior orifice of the choroid is firmly connected to a thick ring of grayish pulpy substance, and forming the point at which the sclerotic and cornea without, and the iris within, are united. This ring, named the ciliary circle (*ligamentum ciliare*), is readily detached from the sclerotic. Its structure is unknown.

Ciliary processes.

Posterior to this is a range of prominent minute bodies, with free extremities, lying over the crystalline lens, varying in number from seventy to eighty. These are the ciliary processes (*processus ciliares*). They are trilateral-prismatic in shape, about a line and a half long, more distinct and longer in the human eye than in those of most brute animals. Their intimate structure is not very well known; but they are highly vascular, and their vessels appear to be capable of occasional erection. (Plate XXX. fig. 4.)

The iris.

Anterior to the ciliary circle is the iris, a circular membrane, placed in the transverse vertical position, with anterior and posterior surfaces, and a circular opening in the centre. The exterior ciliary margin (*annulus major*) is attached, as already stated, to the ciliary circle. The inner or pupillar (*annulus minor*) is free, and forms what is named the pupil of the eye. The anterior surface is marked by a variety of colours, blue, gray, or black, brown, or that peculiar brownish-black named hazel, and which are not unfrequently allied with the tints of the skin and hair. The same surface presents radiating lines, which pass from the small to the large circle diverging. Both appearances are produced by vascular arrangement. The posterior surface of the iris, which has been distinguished as a separate membrane under the name of *uvea*, is covered by the same dark-coloured matter secreted by the choroid, generally more abundant, and of a deeper tint, than the pigment of that membrane. When this is removed by washing, the observer recognises the radiated streaks impressed by the ciliary processes. (Fig. 4.)

Structure of the iris. The different characters of these two surfaces have induced some anatomists to distinguish the iris into anterior and posterior membranes. Though it has some thickness, this is perhaps a fanciful refinement. The anterior surface, which is continuous with the membrane of the aqueous humour, is different from the posterior, which is continuous with the ciliary circle and choroid. The structure of the iris is chiefly vascular, and its vessels have an erectile arrangement.

Its erectile system. The long ciliaries, from which these vessels are derived, divide each at the ciliary body into two branches, which divaricating at obtuse angles, unite with several of the anterior ciliaries, and form with them, beyond the ciliary ligament at the large circumference of the iris, an arterial circle. From this arise smaller branches, which, crossing, unite and form within this a second smaller arterial circle, midway between the ciliary and central margin; and from the concavity of this proceed very minute vessels, which radiate in a flexuous manner, and converge towards the pupil, where, anastomosing most minutely, they form a third circle—the marginal ring of that aperture.

Pupillary contractions, and their true cause. It is chiefly in the middle and inner anastomosing circles that the vessels assume the erectile arrangement; and on this circumstance, and not on that of muscular fibres, so often, so positively, so inconsistently, and so erroneously maintained to exist in the iris, does the mobility of that singular membrane depend. On exposure to direct or bright light, on the application of vinegar, alcohol, or any stimulating substance to the eye, and during the presence of inflammation, the erectile capillaries, distended with blood, are elongated, and necessarily contract the pupillary aperture. In the dark, under the influence of henbane (*hyoscyamus niger*), deadly night-shade (*atropa belladonna*), and some other narcotics, and when the retina is insensible, these vessels seem to lose their faculty of distension, and, perfectly empty and shrunk, allow the pupillar margin to approach the ciliary.

The retina. The retina, which is the third and internal tunic, is of the same shape as the choroid, thin, like cobweb, whitish, translucent, inclining to transparent, and very delicate. Its extreme tenuity and looseness from the choroid causes it to collapse unless inspected under water, when it may be unfolded and expanded for examination. Its outer surface is covered by a very delicate membrane, visible only in a very recent eye, discovered by Mr Jacob of Dublin. It is almost void of red vessels, unless at the part where the optic nerve enters, where one or two from the central artery may be seen. The others are colourless. The assertion that this membrane is an expansion or production from the optic nerve, seems to be gratuitous; for it bears no resemblance to nervous matter, or to the appearance of the optic nerve. It appears to be simply a peculiarly delicate transparent web, fitted to receive the impressions of luminous rays, and to communicate them to the optic nerve, with which it is continuous.

Spot of Sœmmering. On this membrane, about two lines on the temporal side of the optic nerve, and in the axis of the ball, is a circular yellow spot (*macula lutea*), from about a line to a line and a half in diameter, with a minute point or hole in its centre (*foramen centrale*). At this part the retina is much thinner than at any other; and even in the most recent eyes it presents loose folds, which Bichat regards as cadaveric. The yellow spot and its central hole are seen in none of the mammalia except man and the monkeys.

Vitreous humour. The vitreous humour, occupying about three posterior fourths of the eye, is spherical and convex behind and on its lateral circumference, but concave before for receiving the posterior part of the crystalline lens. Contiguous only to the retina, it is attached to the coats by the branch sent from the central artery to the lens. It is transparent, and consists of two parts, an investing membrane, the hyaloid (*membrana hyaloidea*), and inclosed fluid.

Hyaloid membrane. This membrane is not single, but, sending numerous partitions from its inner surface, forms an assemblage of cells in which the fluid is contained. These facts may be demonstrated by incision, bruising the humour, by congelation, or by boiling it. Before, at the outline of the lens, this membrane divides into two folds, one of which is stretched before the capsule, and the other behind. The trilateral-prismatic space resulting from this separation is completed by the capsule, and forms the circular canal of Petit, which is without fluid, and which is demonstrated by inflation. On the anterior fold the ciliary processes are stretched. The structure of the hyaloid membrane is little known; but it is believed to consist of exhalant arteries and colourless veins.

Hyaloid fluid. The hyaloid fluid may be separated from the membrane either by incisions or compressing it between two folds of linen. It then has the appearance of a clear but somewhat viscid fluid, like gum diluted with water. Though rendered slightly turbid by boiling water, acids, and alcohol, it does not coagulate,—a phenomenon which is to be ascribed to the small proportion of albumen which it contains. According to the analysis of Berzelius, 100 parts contain 98·4 of water, ·16 of albumen, 1·42 of muriates and lactates, and only $\frac{1}{50}$th of a part of soda.

Crystalline lens. The crystalline lens, which is transparent and shaped like an oblate spheroid, is situate in the posterior chamber, and in the anterior depression of the vitreous humour, to which the convexity of its posterior surface corresponds. Before also it is prominent and convex; and it is partially covered by the free extremities of the ciliary processes. It consists of two parts, an inclosing capsule and a lens proper.

Capsule. The capsule is usually distinguished into anterior and posterior walls, both covered by hyaloid membrane, both transparent, and both firm and resisting. By boiling water, alcohol, or the acids, it is rendered opaque, whitish, and horny; and it becomes yellow by contact with the air.

The lens, which is perfectly transparent, consists of two portions; an exterior, peripheral, thick, soft, adhesive, and easily removed; an interior, central, solid, and consisting of concentric plates. Both are indurated and rendered opaque by boiling water, alcohol, and dilute acids; but the central nucleus is the firmest. When dried in the air it becomes yellowish, but retains its transparency, and may be preserved for years. These phenomena are to be ascribed to the presence of a peculiar form of albumen. According to the analysis of Berzelius, 100 parts of the substance of the lens consist of 58· of water 35·9 of peculiar matter, chiefly albuminous, 2·4 of muriates, lactates, and animal matter soluble in alcohol, 1·3 of animal matter soluble in water, and 2·4 of membrane.

The lens possesses a high refracting power; and its chief use is to concentrate the luminous rays within the eye, so as to represent distinctly the image of visible objects on the retina. Spherical and transparent in early life, it is flattened and acquires a yellowish tint in old age.

Between the capsule and lens is found occasionally a fluid which has been named *liquor Morgagni*. It appears to be the effect of transudation.

On the structure of the lens, whether organic or not, anatomists vary. Vessels have not been recognised in it; and the most rational view is, that it is the product of an organic action probably in the capsule.

Aqueous humour. The aqueous humour is contained in the anterior chamber, and in that part of the posterior which surrounds the anterior surface of the lens and vitreous humour. It con-

Special Anatomy.

sists of 98·10 parts in the 100 of water, a trace of albumen, and about 2 parts of muriates and lactates of soda. It is contained in a membrane, which lines the posterior surface of the *cornea*, and is supposed to cover the anterior surface of the iris. This, however, is questionable. In 1768 a membrane of this kind was described by Demours and Descemet, both of whom claimed the discovery with great eagerness and some animosity. These rival anatomists appear to have forgotten that the aqueous humour may be secreted as well by the cornea and iris as by a proper membrane.

The relation of the coats and humours of the eye to each other may be understood by the diagram (fig. 3, Plate XXX.), where A is the anterior chamber, P the posterior, L the lens, and c, c the ciliary processes. The other parts are easily understood from the foregoing description.

The eye is supplied with blood chiefly by the ophthalmic artery.

Ocular muscles.

The eyeball, thus constituted, is moved in different directions by six muscles, is moistened externally by fluid secreted from a particular gland, and is protected from external bodies by the eyelids and their appendages.

Of the muscles, four are straight and two oblique. The former (*attollens, depressor, adductor, abductor*), attached to the margin of the optic hole, and terminating in tendons inserted into the superior, inferior, nasal, and temporal parts of the eyeball, raise, depress, adduct and abduct the organ. Of the two latter, the superior oblique (*trochlearis*), which is attached to the margin of the same hole, passes through a pulley-like cartilage at the inner margin of the vault of the orbit, and is inserted into the internal region of the ball, rolls the eye forward and inward, and turns the pupil outwards and downwards; while the inferior oblique, attached to the orbitar process of the superior maxillary bone, and inserted between the adductor and the optic nerve, rolls it forwards and turns the pupil upwards. These muscles, which occupy the apex of the orbit, are surrounded by a thick cushion of fat, on which the eyeball rolls in its movements. (Plate XXXIII. fig. 6.)

Lacrymal gland.

In the hollow, at the outer temporal region of the orbitar vault, is placed the lacrymal gland, a granular grayish body, about the size of a bean, consisting of lobules, with arteries in the intermediate furrows, derived from a branch of the ophthalmic, and accompanying veins. (Plate XXXIII. fig. 5 and 7, G, g.) These constituent lobules have been represented, on the authority of Steno in the ox, and the elder Monro in the human subject, to terminate in 7 or 8 minute excretory ducts, opening on the *conjunctiva*. In man, however, they were sought in vain by Duverney, Morgagni, Haller, and Zinn; and neither Portal nor Bichat have been able to satisfy themselves of the existence of these ducts. It is nevertheless certain that the lacrymal gland secretes the tears, and that the latter issue from its lobules.

Eyelids.

The eyes are covered anteriorly by two musculo-membranous folds named the eyelids (*palpebræ*), attached to the margins of the orbit, and forming by their free margin the palpebral opening, with commissures at each angle (*canthus nasalis, et canthus temporalis*).

The upper eyelid, which is large, is bounded above by the eyebrow (*supercilium*), a cutaneous eminence, arched transversely, covered with hairs, and with the *corrugator supercilii* attached to its nasal end. Between each eyebrow is a smooth space, named the *glabella* or *mesophryon*. Into the upper eyelid the levator (fig. 5, L) is inserted.

Each eyelid consists of skin externally, mucous membrane within (*conjunctiva*), intermediate cellular tissue, muscle, and a fibrous membrane, attached by one margin to the base of the orbit, and terminating by the other in the tarsal fibro-cartilages. These are crescentic bodies placed in the free margin of the eyelids, and by their firmness and elasticity giving the requisite tension to the eyelids when the orbicular muscle acts, or the *levator* is relaxed. The cutaneous border of the *tarsi* is occupied by a range of short, firm hairs, named the eyelashes (*cilia*). In the mucous borders are the orifices of the tarsal or Meibomian follicles, of the same character as the muciparous follicles generally. These are placed in the substance of the eyelid, beneath the *conjunctiva*, and behind the tarsal fibro-cartilages. From the inner surface of the eyelids the palpebral *conjunctiva* is continued over the anterior part of the sclerotic and cornea, forming the ophthalmic *conjunctiva*.

Special Anatomy.

Tarsi and glands.

Caruncle.

In the nasal angle is lodged a minute red body, named the caruncle (*caruncula lacrymalis*), chiefly consisting of filamentous tissue and vessels covered by mucous membrane; and behind this is a fold of the membrane, which has been named *membrana nictitans*, large in the lower animals, but often so imperfect in man as to be merely rudimentary.

Lacrymal orifices.

At the nasal end of each eyelid is a minute capillary orifice which leads into a horizontal canal, terminating in a membranous sac lodged in the depression of the lacrymal bone. These orifices, which are named the *puncta lacrymalia* (*p*, *p*, fig. 5), are the superior or palpebral openings of the lacrymal sac and passages, the lower aperture of which is found in the inferior nasal *meatus*. The tears effused from the lacrymal gland at the temporal region of the orbit are carried, by the frequent action of the orbicular muscle, over the ball, till they reach the nasal angle, where they are gradually absorbed by the capillary orifices of the *puncta*, and conveyed into the sac, and eventually to the nose.

Ocular nerves.

The eye derives nerves from six different sources, all of which, however, may be distinguished into three classes, the sensitive, motive, and entrophic nerves. The first consists of the second, optic or the proper visual nerves. The second class comprehends the third, fourth, and sixth nerves, of which the third or oculo-muscular are distributed to the *levator palpebræ superioris*, the *attollens*, the *adductor*, the *depressor*, and the *obliquus inferior;* the fourth is entirely distributed to the *obliquus superior;* while the sixth pair are confined to the *abductor*. The third class of nerves is derived from the ophthalmic or quadrilateral ganglion, which is formed chiefly from the junction of a sub-branch of the naso-ocular branch of the first or ophthalmic division of the fifth pair, with a small branch of the third nerve. From this arise a small superior cluster of three nerves adhering to the optic, and a large inferior cluster of eight or ten nerves, which quickly join the ciliary arteries, and are with them distributed in the ciliary circle and posterior part of the iris. (Plate XXXIII. fig. 7.) From the other branch of the naso-ocular nerve, the caruncle and lacrymal canal, with the orbicular muscle and *epicranius* on the one hand, and the lacrymal gland on the other, receive nervous filaments.

SECT. III.—THE ORGAN OF HEARING; THE EAR.

The organ of hearing consists of the auricle or external ear, with the ear-hole; the middle ear, including the tympanal cavity and its appendages; and the internal ear or labyrinth.

Auricle.

The auricle is a fibro-cartilaginous substance, moulded into a conchoidal shape, covered by skin, attached to the cranium by ligaments, and susceptible of motion by muscles. It is common to distinguish in it the following parts. The *helix*, a semicircular eminence above the ear-hole; the groove of the *helix* below it; the *antihelix*, an eminence commencing in the groove by a superior, broad,

Special Anatomy.

oblique portion, and an inferior, narrow, horizontal one; the *fossa navicularis;* the *tragus*, an anterior eminence below; the *antitragus*, a smaller eminence behind; the lobule, a pendulous body at the base behind; and, lastly, the *concha*, a deep conoidal cavity leading to the ear-hole.

The latter is a canal about 10 or 12 lines long in the adult. Twisted at first obliquely forward and upward, it bends slightly backwards and downwards, forming a convexity of incurvation above, and a concavity below. Though the extremities are large, the middle is contracted; and it cannot be termed cylindrical, for its section is elliptical or oval. The structure of this tube is fibro-cartilaginous externally where it adheres to the bone, lined by skin passing into mucous membrane, and occupied by minute follicles (*glandulæ ceruminosæ*), which secrete the wax (*cerumen*) formed in this canal. The nature of this secretion is imperfectly known. Though, like oil, it stains paper, it is partly soluble in tepid water, and forms with it a yellow emulsion. It is secreted at first fluid, and acquires consistence by exposure to air and admixture with dust. Alcohol has little influence on it. The internal extremity of the auditory canal is bounded by the vertical membrane of the *tympanum*.

Tympanal cavity.

Within this is the tympanal cavity, a space of an irregular cylindrical shape, directed obliquely, nearly in the axis of the pyramidal portion, in the base of which it is contained. This cavity is shut up externally by the vertical tympanal membrane (*membrana tympani*), and is bounded within by the bony partition which separates it from the labyrinth. The *membrana*, which is oval-shaped, or nearly round, and attached to the margin of the *meatus externus*, is directed obliquely downwards and inwards, and is so delicate that it is difficult to determine its structure in the human subject. In the elephant, however, and other large animals, it presents radiating fibres, which are believed to be muscular (Plate XXXVII. fig. 14); and Sir E. Home represents it as such not only in the elephant and whale, but in the human subject. The outer part is evidently a sort of epidermis, continuous with that of the canal; the inner is a mucous epidermis, continuous with that of the tympanal cavity; and between these the muscular fibres are interposed.

Eustachian tube.

The tympanal cavity communicates behind with the mastoid cells, and before and internally by the Eustachian tube, with the pharynx. This tube is estimated to be two inches in length, of which one and a half is in the bone of the pyramid, and about half an inch at its extremity, with the upper side completed by cartilage. Narrow at the tympanal end, it becomes wide and capacious towards the pharyngeal, and presents at length a free open extremity, forming a fissure at the upper and lateral part of the *pharynx*. The cartilaginous end is covered by mucous membrane continuous with the pharyngeal, and is surrounded by the *peristaphylini*, the action of which is believed to separate the walls of the aperture. Within the tube, and towards the tympanal end, this membrane parts with its pharyngeal spongy character, and becomes thin and semitransparent where it lines the bone. The same kind of membrane, partaking of the characters of periosteum and mucous, is continued over the tympanal cavity, and into the mastoid cells.

Muscle of the malleus and groove.

Above the Eustachian tube is a thin osseous plate, which separates it from a small canal, convex below, concave above, and which, commencing in the fissure between the squamous and pyramidal portions, terminates in the tympanal cavity. In this canal is lodged the internal muscle of the *malleus*, one of the tympanal bones.

Tympanal bones.

These are four in number, very minute, and denominated, from their mechanical figures, the hammer (*malleus*), the anvil (*incus*), the lenticular or round bone (*os orbiculare*), and the stirrup (*stapes*). Of these the *malleus* is attached to the vertical membrane by its handle, while its head is articulated with the body of the *incus*. The latter presents two limbs or branches, to the larger of which the *stapes* is articulated by the interposition of the lenticular bone; while the base of the former rests on the membrane of the *foramen ovale*. These articulations are secured by capsules, which allow the bones to move freely on each other; and for this purpose the *stapes* is provided with one muscle, and the *malleus* with two, an internal already mentioned, and an external passing from the spinous process of the sphenoid bone to the slender process of the *malleus*. On the motions of these, however, and their part in the process of hearing, we have only conjectural statements.

Foramen ovale, fenestra ovalis.

The internal bony wall of the tympanal cavity presents two apertures and a convex intermediate eminence. Of the apertures, the first, which is named the oval or vestibular aperture (*foramen ovale, fenestra ovalis*), is situate above, oval transversely, with its great diameter horizontal antero-posterior. It communicates with the vestibule, but is closed by a fine membrane, to which the base of the *stapes* is fixed, and for the insertion of which its margin is grooved. The oval aperture is bounded above by a round prominence, corresponding within to the Fallopian aqueduct, and below by a large convex eminence named the promontory (*promontorium*), which indicates the situation of the cavity named the vestibule. Before and above the promontory is the extremity of the thin osseous plate which separates the Eustachian tube from the canal of the internal muscle of the *malleus;* and behind is an oblique cavity, which is placed between the lower entrance of the mastoid cells and the pyramid. Below the promontory is the round or cochlear aperture (*foramen rotundum, fenestra rotunda*), trilateral in early life rather than round, and still preserving in the adult the tendency to this shape; smaller than the oval, and directed backwards and outwards. The round aperture is shut by a membrane, the direction of which is oblique to that of the tympanum, and one side of which is towards that cavity, while the other forms part of the *cochlea*.

Promontory.

Mastoid cells.

At the upper part of the tympanum is a triangular-shaped opening, which leads into a rough short canal, terminating in the mastoid cells. These are analogous to the cells of the ethmoid, sphenoid, and occipital bones. They are lined by fibro-mucous membrane, and their use is to afford a posterior sonorous apartment for the vibrations produced in the tympanal cavity.

Near this triangular opening is a small bony process named the pyramidal, in which is a canal for the fleshy part of the *stapedius*, while the tendon issues from its orifice. Near the base of the pyramidal process is the hole by which the nerve of the *tympanum* (*chorda tympani*) passes through the glenoid fissure.

Labyrinth

The labyrinth consists of the vestibule, three semicircular canals, and the *cochlea*.

Vestibule.

By removing the *stapes* and stapedial membrane the oval aperture is opened, and communicates with the vestibule. This cavity, which is irregular in shape, about the size of a grain of barley, is bounded without by the *tympanum*, within by the internal auditory canal, before by the *cochlea*, behind by the semicircular canals, and above and below by the solid bone of the pyramid. It is lined by a membrane common to the whole labyrinth. Besides the oval aperture by which it is separated from the *tympanum*, it has, above, the two anterior openings (*ampullulæ*) of the superior vertical and horizontal canals; behind, the two openings (*ampullulæ*) proper to the posterior vertical and horizontal canals, and the common opening of the

Special Anatomy.

two vertical canals; and before and below, the orifice of the external *scala cochleæ*.

Aqueduct of the vestibule and aperture.

There is still another aperture, which leads into a canal discovered by Cotugno, named the aqueduct of the vestibule. This, which, though distinct in some subjects, is almost imperceptible in others, is near the common orifice of the vertical canals; and from it the aqueduct proceeds first upwards, where it is narrow, then backwards and downwards, widening, and terminates in the fissure on the posterior surface of the pyramidal portion.

Semicircular canals.

The *semicircular canals*, situate behind the vestibule, are three in number, two vertical and one horizontal. Of the former, one is superior, inclosing by its curvature the substance of the pyramid, and forming a convexity in the adult, very distinct in the fœtus; while the other, which is posterior but inferior, is placed with its plane corresponding to that of the posterior surface of the pyramid. The third is placed horizontally between the other two, forming a curvature with the convexity towards the base of the pyramid. (Plate XXXIII. fig. 8, 9, and 10.)

Though denominated semicircular, these canals are larger than semicircular, and may be compared to hollow cylinders, incurvated so as to form large circular segments. Each canal has an enlarged extremity named *ampullula;* and as these two vertical canals have one in common, there are five *ampullulæ*. They are lined by the common labyrinthine membrane, and contain a pellucid fluid.

Cochlea.

The *cochlea*, which forms the third part of the labyrinth, is a conical canal turned spirally within itself, so that its base is at the lower part of the vestibule, and its apex at the anterior side of the pyramid, with the orifices for the auditory nerve inclosed in the centre of its turns, while the convexity is directed towards the lower margin of the pyramid. The cochlear canal is divided longitudinally by a thin sharp-edged plate, half bony half membranous, into two independent cavities, the superior of which communicates with the vestibule, while the inferior is bounded by the membrane of the round aperture. These cavities are distinguished as the vestibular and tympanal (*scala vestibuli* and *scala tympani*) respectively. At the top they terminate in a common cavity named the funnel (*infundibulum*). Both are lined by a delicate membrane, in which are contained the ramified filaments of the eighth or auditory nerve. (Plate XXXIII. fig. 10.)

Aqueduct of the cochlea.

In the tympanal *scala*, near the round hole, is a minute aperture leading to a narrow canal, which gradually enlarges as it ascends, till it terminates by a slit on the posterior surface of the pyramidal portion, as formerly mentioned. This is the aqueduct of the *cochlea*, first described, like that of the vestibule, by Cotugno.

Blood-vessels of the ear.

These different cavities are supplied with blood chiefly from minute branches of the auditory, a vessel generally derived from the basilar trunk or the vertebral arteries. From the meningeal artery also minute branches enter the auditory canal, and anastomose with those of the auditory artery; and the internal carotid sends to the membrane of the tympanal cavity a branch, the capillary ramifications of which anastomose with those derived from the pharyngeal, transmitted by the walls of the Eustachian tube.

Auditory nerve.

The eighth or the proper auditory nerve enters the cochlea by several minute apertures in the internal *meatus*, and is divided into two *fasciculi*, of which the posterior and largest is expanded in the form of soft pulpy brush-like filaments, like a hair-pencil, in a pellucid fluid, in the *cochlea;* while the smallest, which is anterior, is distributed partly to the bottom of the hemispherical cavity of the vestibule, partly to the beginning of the spiral lamina. (Fig. 10.)

The tympanal cavity is chiefly for the purpose of conveying and augmenting the intensity of sonorous vibrations, while the shape of the auricle is supposed to collect them. But of the mechanism of its operation we know nothing satisfactory. The essential part of the organ of hearing is the labyrinth.

SECT. IV.—THE ORGAN OF TASTE.

It is impossible to define the exact limits of the sense of taste. More or less diffused over the cavity of the mouth, it is particularly confined to the tongue and palate. The former, nevertheless, is remarkable for being a muscular organ, which combines with the faculty of taste the power of prehension and transmission of the alimentary articles both during and after mastication, and is further an essential agent in the faculty of articulation. It is requisite, therefore, to give a short account of the mouth, the palate, and the tongue.

The mouth.

a. The mouth is the cavity formed by the lips before, the *pharynx* and *isthmus faucium* behind, the palatine vault above, the intramaxillary membrane and muscles below, and on the sides by the cheeks. Its horizontal direction may be regarded as one among other proofs of the necessity of the erect biped attitude.

The mouth is lined by a mucous membrane, soft, spongy, red, and vascular. It may be traced from the inner or alveolar surface of the lips to the inner surface of the cheeks on each side over the gums, where it is continuous with that of the alveolar *folliculi*, over the inner surface of each maxillary *ramus*, and the attached muscles and glands below, until it is identified with that of the tongue, and above over the palatine vault back to the *uvula*. In these several points, though its organization is the same, its mechanical arrangement varies considerably as the parts are fixed or movable. Thus, on the palatine vault and at the gums it is tense, and adheres pretty firmly to the fibrous layers forming the periosteum of these parts. In the angular space between the lips and gums, however, in that between the inner surface of the alveolar arch, and all over the lower part of the mouth, where it is connected to the inferior surface of the tongue, it is extensive, loose, moves easily over an abundant layer of filamentous tissue, and is generally disposed in irregular folds. Adhering to the internal spine of the lower jaw, a fold or duplicature containing condensed filamentous tissue is reflected, to be attached to the median line of the tongue, and forms the *frenum* of that organ. In all points it abounds with muciparous follicles. It also presents on each side of the tongue the orifices of the sublingual glands.

Outlets of the mouth.

The mouth has two outlets, an anterior or facial formed by the lips (*labia*), and a posterior or pharyngeal formed by the *velum palatinum* and its appendages.

The lips.

The lips are musculo-membranous folds, attached all round to the superior and inferior jaw-bones, above and below the alveolar arches, and parted by a transverse opening or fissure into upper and lower, with right and left commissures or angles (*canthi*). In the Negro race they are particularly bulky and flaccid, with their free margins (*prolabia*) much everted; but in the Asio-European they are thinner, and more constricted.

Each lip consists externally of skin continuous with that of the face, internally of mucous membrane continuous with that of the mouth, with interposed filamentous tissue and muscles, well supplied by blood-vessels and nerves.

The point of union between the skin and oral mucous membrane is marked by a rounded edge, covered by a thin, vermilion-red, soft and delicate pellicle, extending between

Special Anatomy.

each *canthus*. This, which is sometimes named the lips proper (*labiola*), is the *prolabium*. The blood-vessels distributed to this part of the lips have an erectile arrangement. The marginal region of the lips between the skin and mucous membrane is occupied by the orbicular muscle. Above are the labial ends of the common levators (*levator labii superioris alæque nasi*), the proper levators (*levator labii superioris*), the small zygomatics (*zygomaticus minor*), and the naso-labial (*nasalis labii superioris*). Below are the two depressors of the lower lip. At the angles are placed the buccinators, the depressors of the angles, the canine muscle (*levator anguli oris*), and the large zygomatics.

The lips are supplied with blood from the branches of the external carotid. The external maxillary sends a large branch over the angle of the inferior jaw, upwards and forwards to the labial commissures on each side. This vessel, which is generally named the labial, sends off two, a superior and inferior labial, which are subdivided into numerous minute branches, anastomosing freely with each other, and with the submental and inferior dental branches. They open freely into the capillary veins, constituting a species of erectile tissue.

The lips derive their nerves partly from the superior maxillary, partly from the anterior or mental division of the inferior maxillary, with anastomotic communications from the 8th or facial nerve.

Soft palate.

b. The posterior or pharyngeal outlet of the mouth (*isthmus faucium*) is formed by the movable or soft palate (*velum palatinum*), a membranous fold attached to the posterior margin of the palatine quadrilateral bones, and hanging with its free margin downwards. This curtain, which has two surfaces, an anterior or oral and a posterior or pharygneal, is shaped like a double arch, meeting on the mesial plane, where it terminates in an elongated conical prominence, supposed to resemble a grape suspended by its stalk, and denominated therefore *uvula* (σταφυλη), but which, with the lateral arches, bears a closer resemblance to the descending cusp of a Gothic window. From this central process the arch rises on each side; and when it passes to the outer edge of the palate-bone on each side, it is supported by two musculo-membranous vertical columns, united at the top, but separating and forming an intermediate cavity, in which the tonsil on each side (*amygdala*) is contained.

The palatine curtain consists of two folds of mucous membrane, with interposed filamentous tissue and muscular fibres. The anterior mucous membrane is of the same character with that of the mouth, with which it is continuous. The posterior, which is continuous with the nasal mucous membrane, partakes of the characters of that tissue, and is redder and more vascular. These two meet in the lower margin of the *velum*, and pass into each other. Both are well supplied with mucous follicles, but the anterior or oral division most copiously.

These mucous membranes rest on filamentous tissue; and beneath this we find, in the middle, the *levator* or *azygos uvulæ*, and on the sides the levator of the soft palate (*peristaphylinus internus*), which are expanded in the *velum*. The anterior pillar consists of mucous membrane enveloping the fibres of the *constrictor isthmi faucium;* the posterior incloses those of the *pharyngo-staphylinus;* and both expanding into the *velum*, augment its thickness and regulate its motions.

Between the internal *peristaphylini*, which are immediately below the pituitary or posterior mucous membrane of the velum and the anterior, is an aponeurotic web, connected with the *circumflexi*, which, fixed to the margin of the palatine vault, tends to consolidate the *velum*.

The free margin of the *velum* forms the upper boundary of the posterior or pharyngeal opening of the mouth, while the upper surface of the base of the tongue forms the lower boundary. The size of this opening, which is usually named the isthmus of the throat (*isthmus faucium*), varies according to the state of the *velum* and its *uvula*. In the act of deglutition the *velum* and *uvula* are raised by the *peristaphylinus internus* and *azygos uvulæ*, and the whole curtain is constricted by the *constrictor isthmi faucium* and *pharyngo-staphylinus*. In the act of vomiting it is forcibly drawn up against the posterior nasal openings by these muscles; but notwithstanding this, matters from the stomach are occasionally projected through the nostrils. In singing on false notes the *uvula* is progressively elevated, as the voice ascends.

In the space between the anterior and posterior pillars are contained the tonsils (*tonsillæ, amygdalæ*), bounded above by the commissure of the pillars; below by the lateral part of the base of the tongue, where they are continuous with the muciparous glands of that organ; before by part of the *constrictor isthmi faucium;* and behind by the *pharyngo-staphylinus*. The shape varies in different individuals, though their pendulous attachment gives them the oblong spheroidal or almond-like shape. They consist of several lobules, grayish, soft, and of structure similar to that of the muciparous glands of the tongue. The lobules present minute cavities, isolated or mutually communicating, in the recess of which are minute pores, the orifices of the excretory ducts, and from which a watery but viscid liquor may be expressed. In short, each tonsil may be regarded as an assemblage of muciparous glands, destined to secrete fluid for lubricating the throat during the process of deglutition, when it is most abundant.

The chops (*buccæ*) or lateral walls of the mouth consist externally of skin, internally of mucous membrane and of an intermediate layer of muscles imbedded in abundant filamentous and adipose tissue.

The cutaneous covering is in general thin, soft, and peculiarly smooth, with a minutely distributed and abundant capillary system, which approaches in its characters to the erectile.

Beneath the cutaneous covering is the *zygomaticus major*, the only muscle proper to the cheek, resting on a thick layer of fat; below this is the *buccinator*, perforated by the parotid duct; and to the filamentous tissue inside, the buccal mucous membrane, furnished with numerous muciparous follicles, adheres. The orifice of the parotid duct is seen opposite the second molar tooth of the superior jaw.

The tongue.

c. The tongue is a longitudinal muscular organ, invested by a mucous membrane provided with numerous *papillæ*, attached behind to the hyoid bone, below to the mucous membrane of the mouth, and free above and before It is shaped like a flattened cone, and is distinguished into a base and tip (*apex*), an upper and a lower surface and two sides.

The base is somewhat thick and broad, but becomes thin and narrow near the hyoid bone. From about 1 inch anterior to this, however, to near 1½ from the tip, the thickness and breadth are nearly uniform. The tip (*apex*) is flat and rounded or paraboloid in ordinary circumstances, but may be made by muscular action to taper to an angular point. The upper surface, which is free, presents the lingual mucous membrane divided into right and left halves by a superficial furrow. On this, near its posterior end, is a depression, variable in size, named the *foramen cæcum*, in which are contained the orifices of muciparous follicles. From this on each side proceeds an oblique line diverging forward, and forming with that of the opposite side an acute angle, with the angular point behind. These an-

Special Anatomy.

gular ines, which are variable in shape and disposition, depend on the elevation resulting from the mucous glands at the base of the organ. The rest of the surface presents the minute conical eminences named *papillæ*, which belong to the mucous membrane. The lateral margins, which are smooth and void of *papillæ*, form the transition from the upper free papillated surface to the lower, which is chiefly attached by folds of the oral membrane to the lower region of the mouth.

The tongue consists of various muscles, connected by filamentous tissue, some adipose tissue, and invested by mucous membrane.

Muscles. The muscles are of two orders, those common to the tongue and contiguous parts, and those proper to the tongue. The common or extrinsic muscles are, the *styloglossi*, between the styloid process and margins of the tongue; the *hyoglossi*, between the branches of the hyoid bone and the margins of the tongue; and the *genioglossi*, from the upper internal mental tuberosities to the lower part of the organ. The proper or intrinsic muscle (*lingualis*) consists of two parallel layers of muscular fibres running along the lower surface of the organ, and a mass of fleshy fibres irregularly arranged and mutually crossing in all directions, and intermixed with a considerable quantity of soft but elastic oleo-adipose matter.

Of the lingual mucous membrane the most important circumstances are, the leathery thickness and distinctness of its corion and epidermis on the superior surface of the organ, and the papillary eminences with which it is marked.

Lingual papillæ. These *papillæ* may be distinguished into three orders; the irregular or granular at the base, the tubercular or rounded about the middle third, and the conical or pointed at the apex.

The granular *papillæ*, which vary in number from 10 to 15 or 16, are of a spheroidal or ovoidal shape, and are arranged on each side of the median furrow, obliquely behind the sides of the angle already mentioned. These bodies are evidently muciparous follicles; and it is in general easy to distinguish the orifice of the excretory duct by the eye or a moderate lens. They seem to receive filaments from the glosso-pharyngeal nerves, which enter the tongue immediately beneath these granular glands.

The tubercular *papillæ*, which are much more numerous, have rounded truncated summits, and occasionally pedunculated stalks. They are irregularly distributed towards the middle, margins, and apex of the tongue, promiscuously with the conical; and their nature is unknown.

The conical or acuminated *papillæ*, though occupying the two anterior thirds of the lingual surface, are nevertheless most numerous towards its apex, where they are also smallest, and somewhat inclined forward. These *papillæ* are asserted by the older anatomists to be the terminations of nervous twigs; and Cloquet allows them to be the expansion of the filaments of the lingual nerve. This, however, is an evident relic of the fanciful representations of the older anatomists, and is not supported by inspection. I have examined the structure of the lingual *papillæ* in many instances, and in none have I seen any ground for the assertion that they consist of nervous filaments. They do not even receive a larger proportion than other parts of the lingual membrane. The *papillæ* consist chiefly of numerous minute blood-vessels, rather tortuous, and communicating directly with veins enveloped in fine filamentous tissue; and from this they derive their property of erection, while their mucous surface secretes mucus copiously. These *papillæ* are further the seat of the white fur with which the tongue is liable to be coated in affections of the stomach. The yellow fur seems to be produced from the mucous surface generally.

Arteries. The tongue is supplied with blood by the lingual arteries, branches of the external carotids, and by the palatine and tonsillary of the external maxillary. The blood is returned by the superficial vein, the ranine, the lingual, and submental.

Nerves. The nerves of the tongue are derived from three different sources; the inferior maxillary, or third branch of the fifth pair; the glosso-pharyngeal; and the hypoglossal. From the first it receives the lingual nerve, which, after sending filaments to the sublingual gland, the *styloglossus*, *genioglossus*, and proper muscle of the tongue, is distributed chiefly to the upper surface, sides, and apex of the organ. This is believed to be the proper *gustatory nerve*. From the second it receives a lingual branch, which, passing between the *styloglossus* and *hyoglossus*, gives filaments to these, the proper muscle, and the posterior part of the *genioglossus*, and to the granular *papillæ*. By means of this nerve the motions of the tongue and pharynx are made to associate. The third, which is distributed chiefly to the muscles attached to the hyoid bone, sends filaments also to the *hyoglossus*, *styloglossus*, and chiefly to the *genioglossus*. The hypoglossal is believed chiefly to preside over the motions of the tongue, and probably those destined for articulation.

Uses. The tongue is one of the best examples in the human body, of the felicity with which a single organ may be adapted to a great variety of useful purposes. Endowed with the common sensation of tact, diffused over the body at large, its mucous investment is so organized that it recognises readily the peculiar impressions communicated by sapid bodies. To render it more serviceable in this respect, its muscles make it an organ of prehension, and elongate, contract, inflect, incurvate, or extend it, so as to apply objects placed on its tip to the palate or any part of the mouth. By the same means it becomes an important agent in the prehension of food, and in deglutition, by transmitting the masticated food to the pharynx. Lastly, it is a most essential and necessary organ of speech, and, by the nice motions which it undergoes, enables the human race to pronounce literal sounds and articulate consonants, which without its aid would be unutterable. Of this the letters l and r are examples.

Salivary glands. d. Connected with the organs of taste are the salivary glands, of which there are three pairs, one on each side of the mesial plane; the parotid, submaxillary, and sublingual.

Parotid. The parotid, so named from its situation before the ear, is the largest of all the salivary glands. It consists of two parts, the parotid proper, a large oblong mass placed in the deep angular cavity formed by the maxillary *ramus* and the mastoid process; and the *socia parotidis*, a large flat irregularly oval mass extending beneath the skin of the face. Partaking of the general characters of glandular structure, it is supplied with blood from the external carotid, by the temporal and transverse facial; its veins open into the external jugular; and it receives numerous nervous filaments from the facial and the ascending branches of the cervical plexus.

It has an excretory duct, named also the duct of Steno (*ductus Stenonianus*), which, quitting the surface of the gland a little above the middle of the upper margin of the *masseter*, proceeds horizontally over the tendinous part of that muscle, and, sinking into the filamentous adipose tissue of the cheek, perforates the *buccinator*, and terminates in the mouth at the level of the second superior molar tooth.

Sub-maxillary. The submaxillary or intramaxillary is smaller than the parotid. Oblong in shape, it is placed on the internal pit

Special Anatomy.

of the lower jaw, bounded by the internal pterygoid and mylo-hyoid above, the lingual nerve, the *stylo-glossus* and *hyo-glossus*, and the external maxillary artery behind, and below by the *latissimus colli* and integuments. Blood it derives from the lingual and external maxillary arteries, and nerves from the lingual and the myloid branch of the inferior dental. Its excretory duct, named, from its discoverer, *the duct of Wharton*, terminates on the side of the *frenum*, in a narrow tuberculated orifice.

The sublingual gland.

The sublingual gland is the smallest of the three. Parallel to that of the opposite side, it is separated from it by the base of the two *genio-glossi*, and rests on the *mylo-hyoideus*, which separates it from the intramaxillary. Occasionally, however, these two glands communicate by a slip from the intramaxillary below the muscle. It is supplied with blood by the sublingual, ranine, and submental arteries; and its nerves proceed from the lingual and hypoglossal. Its excretory ducts are manifold, and terminate either in several orifices on the sides of the *frenum*, or unite in a single tube, opening in the same region.

The use of these glands is to separate from the blood a watery but somewhat saline and sapid fluid, which has the twofold office of preserving the gustatory membrane in its necessary moisture, and of mixing with the food during mastication.

The *saliva* consists chiefly of water, holding in solution hydrochlorate of soda, sulpho-cyanic acid, and a minute portion of animal matter intermediate between albumen and osmazome. The presence of sulpho-cyanic acid, an active poison, is remarkable; nor is the purpose of such an agent known. From the saline matters in this fluid the tartar of the teeth is deposited; and occasionally minute concretions are formed in the glands or their ducts. That appearing in the ducts of the sublingual forms one variety of the affection named *ranula*.

CHAP. III.—THE ORGANS OF VOICE.

Voice is of two kinds, according as it consists in the mere voluntary utterance of sound, or what is named, in reference to the animal world, *cry*, or in the utterance of certain peculiar modifications of this, denominated therefore articulate voice, or simply speech. Inarticulate voice is common to all the MAMMALIA and BIRDS. By the possession of articulate speech, however, man (μεροψ) is particularly distinguished from the animal world in general.

These two forms of voice have two distinct organs. For inarticulate voice the *larynx* is placed at the superior extremity of the windpipe; and for that of speech, to the larynx are superadded the articulating powers of the teeth, lips, and tongue.

The larynx.

The larynx is a tubular organ, consisting of cartilages invested by membranes, connected by ligaments, and moved by muscles.

Thyroid cartilage.

The cartilages are five in number, the thyroid, cricoid, two arytenoid, and the epiglottis.

The thyroid cartilage, which forms the anterior and lateral region, consists of two lateral halves united on the mesial plane, where they form an acute salient angle, distinct beneath the integuments, and forming what is named the *pomum Adami*. The anterior surface is slightly concave, covered by the *thyro-hyoideus*, with an oblique line, to which the muscle now mentioned, the *sterno-thyroideus*, and inferior *constrictor*, are attached, and a posterior space covered by the two latter muscles. The posterior surface of the thyroid has in the middle a re-entrant angle, to which are attached the ligaments of the *glottis* and the *thyro-arytænoidei;* on the sides two plane surfaces, corresponding above to the cellular tissue of the *thyro-arytænoidei*, and below to the lateral *crico-arytænoidei*, and some fibres of the *crico-thyroidei* attached to this part.

Each lateral half is quadrilateral and quadrangular. To the upper margin, which is obliquely sinuated like an *f*, the thyro-hyoid membrane is attached. To the lower, which though shorter is also sinuated, the crico-thyroid membrane and the *crico-thyroidei* are attached.

The posterior margins, which are oblique and give attachment to several fibres of the *stylo-pharyngei* and *palato-pharyngei*, terminate above in an elevated pointed process incurvated inwards and forwards, connected by a ligament to the hyoid bone, and below in a similar process, shorter however and triangular in shape, and articulated by its tip with the lateral process of the cricoid cartilage.

Cricoid cartilage.

The cricoid or annular cartilage (κρικος, *annulus*), which occupies the lower part of the larynx, is a complete ring of cartilage, narrow before, and broad and elevated behind, where chiefly it constitutes the laryngeal cavity. Convex in the middle, where it is subcutaneous, it widens laterally where the *crico-thyroidei* are attached; and farther back, where it is covered by the thyroid cartilage, it presents the lateral process covered by synovial membrane for articulation with the triangular process of the thyroid. Its posterior region is broad and quadrilateral, with a ridge on the median line covered by the pharyngeal membrane only, and two depressions on each side, to which the posterior *crico-arytænoidei* are attached. The inner surface, which is concave, narrow before and broad behind, is covered by the laryngeal mucous membrane.

The superior margin presents before a large notch, to which the crico-thyroid membrane is fixed, laterally the insertion of the lateral *crico-arytænoidei*, and behind two convex surfaces, oblique in direction, covered by synovial membrane for articulation with the arytenoid cartilages, and between which this margin is covered by the arytenoid muscle. The lower margin, less irregular, descending before, sinuated on the sides and notched behind, is united by a fibro-mucous membrane to the first ring of the windpipe.

Arytenoid cartilages.

The arytenoid cartilages are two small bodies, triangular and pyramidal in shape, placed at the posterior part of the larynx, in the upper margin of the cricoid cartilage. In each arytenoid cartilage may be recognised a concave anterior surface for the arytenoid gland, a concave posterior surface for the arytenoid muscle, an internal surface covered by laryngeal mucous membrane, a base concave and oval, covered by synovial membrane for articulation with the cricoid, and a thin, convex summit, supporting a small cartilage (*cornicula laryngis*), invested by mucous membrane.

The tubercles of Santorini.

These bodies, which are named the tubercles of Santorini (*capitula arytænoidum*) by whom they were discovered, are conical in shape, with a concave base for articulating with the summit of each arytenoid cartilage, and a pointed *apex* incurvated inwards and backwards. To their surface, with part of the arytenoid, the thyro-arytenoid ligament is fixed, and forms the beginning of the *glottis*.

These bodies partake of the general characters of cartilage, and are invested by perichondrium. The thyroid and cricoid have a great tendency to ossification; and it is rare to find them unossified in advanced life.

The epiglottis.

The epiglottis is a thin slip of fibro-cartilage, of a paraboloid shape, covered by mucous membrane, attached at its base by cellular tissue to the inner surface of the hyoid bone and the upper margin of the thyroid cartilage, and by duplicatures of mucous membrane to the summits of the arytenoid cartilages. In this duplicature, on each side, is suspended a minute wedge-like cartilaginous tubercle, with the base upward, named the *cuneiform*.

The cuneiform cartilages.

These cartilages are articulated so as to admit of mo-

tion at the points already indicated. The articulations are secured by ligamentous capsules; but the most important ligament is the thyro-arytenoid, which passes from the base of each arytenoid cartilage to the re-entrant angle of the thyroid, where the fibres are mutually mixed with that of the opposite side. The thyroid moves on the cricoid, which may be regarded as the base of the organ; and the two arytenoid move on the upper margin of the cricoid. The epiglottis is depressed over the laryngeal opening by the motion of the tongue in deglutition.

The agents of motion in the larynx are of two kinds; 1*st*, those which move the whole organ in relation to the neighbouring parts; and, 2*dly*, those which move the component parts of the larynx in relation to each other. To the former class belong the sterno-thyroid, thyro-hyoid, and inferior constrictor muscles, with those attached to the hyoid bone, the elevation and depression of which the larynx follows. The second comprehends the crico-thyroid, the posterior crico-arytenoid, the lateral crico-arytenoid, the thyro-arytenoid, and the arytenoid. The connections and relations of these muscles it is superfluous to detail more minutely than may be understood from the description already given of the cartilages. It is sufficient to say, that while the crico-thyroid causes the thyroid cartilage to perform a swinging motion on the cricoid, the posterior crico-arytenoid draws the arytenoid cartilages back, the thyro-arytenoid draws them forwards, the lateral crico-arytenoid separates them from each other, and the arytenoid, sometimes distinguished into transverse and oblique arytenoid muscles, approximates these cartilages in different degrees, according to the act in which they are used.

The several parts now mentioned are invested on the inside by mucous membrane, continuous above with that of the pharynx and tongue, and below with that of the trachea. Proceeding from the former boundary, it may be traced over the epiglottis and its gland, on the mesial plane and the *thyro-arytænoidei*, and on the sides from the inner surface of the thyroid cartilage before to the outer margin and base of the arytenoid cartilages behind. At this part it rises to form two folds with rounded margins, extending from before backwards, and forming on the outsides a cavity with the arytenoid cartilage. These folds, though occasionally named the *superior ligaments* of the *glottis*, are truly mucous membrane doubled, with interposed filamentous tissue. They form an intermediate triangular space, with the base before and the apex behind. The inner surface of this membrane, directed to that of the opposite side, is concave, and forms a sort of pouch called the *ventricles* of the larynx (*sacculi laryngis*). The membrane here covers the thyro-arytenoid ligaments, over which it is tensely stretched, so as to form inferior folds, much tenser and firmer than the superior ones. These lower folds, which form a triangular interval with the base behind and the apex before, are the proper ligaments of the larynx, or vocal chords (*chordæ vocales*); and the intermediate fissure is named the *glottis*, or *rima glottidis*. Though this opening is triangular in the dead body, its shape varies much in the living. By the joint action of the posterior *crico-arytænoidei* and the *arytænoidei transversi*, the thyro-arytenoid ligaments may be rendered tense, the arytenoid cartilages approximated, and the fissure of the glottis become a mere slit.

Though it is impossible to adopt all the views of Dodart regarding the powers of the thyro-arytenoid ligaments, it is certain that their tension and relaxation, with the mutual approximation of the arytenoid cartilages, are the essential agents of voice. Without the air passing through the glottis there is no voice. The glottis is also the organ by which the quantity of air admitted into the *trachea* is regulated. By means of its muscles it may be shut, and the breath retained, so as to fix the chest during any great effort. By contracting it, also, during coughing or forcible expiration, the air is forcibly expelled from the lungs, and necessarily carries at the same time foreign bodies.

At the base of the epiglottis, in the angle between it and the thyroid, the laryngeal membrane presents several orifices, which may be traced to a cluster of follicles imbedded in the submucous tissue at this part. This cluster has been named the epiglottic gland.

A similar glandular body, in the anterior depression of each arytenoid cartilage, is named the arytenoid glands.

Of the body named thyroid gland, situate on the sides of the upper end of the *trachea*, and generally referred to the appendages of the larynx, nothing is known. With the larynx it has certainly no relation.

The blood-vessels of the larynx are the superior thyroid or laryngeal, the first branch of the external carotid, and the inferior laryngeal branch of the inferior thyroid, the second branch of the subclavian artery.

The nerves are derived from the pneumogastric or *nervus vagus*, and may be referred to three divisions; the *internal laryngeal*, distributed to the proper muscles of the larynx; the *external laryngeal*, distributed to the *thyro-pharyngeus*, the sterno-thyroid, hyothyroid, and crico-thyroid; and the *recurrent*, distributed to the laryngeal membrane. the thyro-arytenoid, and posterior crico-thyroid muscles. The division of these nerves, or of the pneumogastric, from which they proceed, is followed by palsy of the muscles, and inability to open the glottis at will, or retain it open; and the result is dyspnœa, terminating in asphyxia

CHAP. IV.—THE NERVOUS SYSTEM.

The nervous system includes two general divisions, a central and a distributed. The first is collected in a single and indivisible mass, contained in the cavities of the cranium and vertebral column, and may be designated by the general appellation of brain (*cerebrum*). The second consists of long chords connected with some part of the central portion and with each other, and distributed in every direction through the body in the mode of ramification. These are distinguished by the name of nervous chords or nerves (*nervi*).

SECT. I.—THE BRAIN AND ITS MEMBRANES.

§ 1. THE BRAIN. Plate XXX.

The brain may be considered as a continuous organ, consisting of three divisions;—the convoluted, the laminated, and the smooth or funicular portions. Of these divisions, which are framed according to the peculiar external configuration of each, the first part corresponds to what is called the brain proper (*cerebrum*); the second to the small brain (*cerebellum*); and the third to the oblong body contained in the vertebral column, and known under the name of *spinal chord*.

The convoluted portion presents two surfaces, an outer or convoluted, and an inner or figurate. The laminated portion in like manner presents two surfaces, an outer or laminated, and an inner or central. The third has only one exterior surface.

The shape of the first two divisions is like that of the cranial cavity in which they are contained, oblong spheroidal or ovoidal, with the small extremity of the ovoid before, and the large one behind.

The human brain is larger and heavier in proportion than that of any other animal. The three parts, the brain, cerebellum, and spinal chord, after being washed and

emptied of blood, weigh in the adult from two pounds five ounces to three pounds three ounces, and at an average about three pounds; and of this the brain alone weighs two pounds. The statement of Haller, that the brain weighs five pounds, is incredible, unless it be understood of Troy weight, in which case even it seems exaggerated, since of more than 200 brains weighed by Soemmering, not one amounted to four pounds. The statement, that the brain of Cromwell weighed six pounds and one fourth, seems equally incredible. The specific gravity of the adult brain is to water as 1031 to 1000. This, however, varies with age. The cerebellum weighs about five or six ounces, and is therefore about the seventh part only of the weight of the brain.

General division of the brain.

The brain (*cerebrum*) is divided above and before into two lateral halves, named hemispheres (*hemisphæria*), right and left, separated by a deep furrow, in which the vertical, crescentic, or dichotomous portion (*falx*) of the hard membrane is received. Each hemisphere is bounded by a superior or convex, an inner or plane, and an inferior convex and concave surface. The lower surface of each hemisphere, also, anatomists distinguish into three lobes, an anterior, posterior, and middle.

The cerebellum is also divided into two hemispheres, separated by a middle furrow of less depth, receiving, as that of the brain, a crescentic production, smaller in size, from the hard membrane.

Convoluted surface of the brain.

The exterior surface of the convoluted division is formed into eminences longitudinal and rounded, but directed in various ways, named convolutions or circumvolutions (*gyri*, Soemmering, Wenzel), and separated from each other by deep hollows (*sulci*). To see this surface, which is termed the *convoluted*, the vascular membrane termed *pia mater* (*meninx tenuis*) must be removed.

The convoluted surface of each hemisphere may be divided into five regions: 1. The commutual or dichotomous; 2. the lateral-superior or convex; 3. the antero-inferior or frontal; 4. the medio-inferior or spheno-temporal; and 5. the posterior or cerebellic region.

1. The *commutual,* plane, of a shape nearly semicircular, forms the mesial boundary of each hemisphere, and corresponds to the falciform or dichotomous portion of the hard membrane (*μηνιγξ σκληρα, meninx dura*), by which it is separated from the similar surface of the opposite hemisphere. Before and behind it extends from the superior to the inferior surface of the brain; but a considerable portion of its middle is terminated by the upper surface of the middle band (*mesolobe, corpus callosum*), which lies between the two hemispheres. It is contained between the semicircular and the rectilinear margins.

2. The *convex* region occupies the anterior, upper, lateral, and posterior parts of the hemisphere, from their anterior to their posterior extremity, and from the semicircular margin to a line which extends between these extremities along the lateral borders of the organ.

3. The *antero-inferior* or *frontal* rests on the horizontal part of the frontal and ethmoid bones, commencing before with a curved outline, bounded behind by the curvilinear hollow named the fissure of Sylvius, and at its inner or mesial margin by the great fissure which separates the hemispheres. This inner margin presents one convolution, consisting of a longitudinal eminence, extending in the adult brain about 1½ inch from the posterior towards the anterior end of the notch. The outer furrow contains the cerebral portion of the first pair or olfacient nerves. (1, 1.)

4. The *medio-inferior* or *spheno-temporal* is situate immediately behind this region, from which it is separated by the curvilinear hollow (*fossa Sylvii*). In the ordinary descriptions this forms the *middle lobe;* while the posterior part, corresponding to the *cerebellum,* though distinguished by no evident limit, is with equal impropriety named the *posterior lobe.* The whole region, from the curvilinear hollow to the posterior tip of the hemisphere, may, however, be subdivided into two, the *medio-inferior* and *postero-inferior* regions of the convoluted surface, according as they correspond to different containing parts.

5. The *posterior cerebellic region* of the convoluted surface, which is plane, corresponds to the horizontal or cerebellic part of the hard membrane.

The convoluted surface is formed of cerebral matter, of a gray or dirty wax colour, the surface of which is smooth and polished where it has not been rent by the removal of the membranes and their attachments. In the furrows are many minute orifices, into which the soft membrane (*λεπτη μηνιγξ, meninx tenuis, pia mater*) transmits filamentous bodies, containing minute blood-vessels.

Neither the eminences nor the hollows are uniform in number or distribution; and in no two brains is it possible to trace any similarity in their figure, presence, or direction, in the upper, lateral, and posterior part of the convoluted surface, unless where it approaches the central or figurate surface, where a number of important objects are presented.

The convoluted surface communicates with another interior surface at two parts; 1*st*, on the middle plane, under the posterior end of the middle band or mesolobe (*corpus callosum*); 2*d*, on each side of the middle plane, at the outer margin of the fluted masses termed *limbs* of the brain (*crura cerebri*), between these limbs and the posterior end of the optic chamber or couch (*thalamus opticus*). This surface of the organ may be termed the *central* or *figurate.*

Laminated surface of the cerebellum.

The exterior surface of the cerebellum consists of thin portions of cerebral substance named plates (*laminæ*), or leaves (*folia*), placed contiguously, either parallel or concentric, and separated by furrows of various depth. This surface, which may be named the *laminar* or *foliated* surface of the small brain, communicates also with the figurate surface,—1*st*, above on the middle plane, between the semilunar notch behind, and the white cerebral plate termed Vieussenian valve before; 2*d*, at its inferior surface, between the almonds or spinal lobules above, and the upper end (*medulla oblongata*) of the spinal chord below.

The outline of each hemispherical surface of the *cerebellum* describes three fourths of a circle; and as the segments mutually meet towards the mesial plane, the mode of union varies according to the figure of the objects to which they are adapted. 1*st*, The hemispherical border, approaching the anterior part of the organ, is suddenly interrupted where the cerebellic peduncles (*crura cerebelli*) are connected with the protuberance; and, pursuing a retrograde direction on each side towards the mesial plane, forms a re-entrant curvature or notch—the *semilunar*—corresponding to the lower pair of the bigeminous bodies.

Semilunar notch.

2*d*, The hemispherical borders, approaching the posterior part of the *cerebellum,* proceed, near the mesial plane, by an acute circular turn, almost straight backwards, and form, at the posterior edge of the organ, a deep rectangular notch,)(, not unlike the figure of the ancient lyre, named the *perpendicular fissure* of Malacarne, or *the purse-like fissure* of Reil, and containing the cerebellic vertical portion of the hard membrane (*falx cerebelli*).

Purse-like notch.

Between these two boundaries the cerebellic plates, of which the hemispheres consist, are united in the middle by an interlacement, named suture (*raphe*), of the cerebellum. A large hollow between the hemispheres, extending backwards from the semilunar to the purse-like fissure, is the small valley (*vallecula*) of Haller.

Special Anatomy.

Cerebellic lobes.

Each hemispherical surface consists of five lobes; 1. the anterior-upper or quadrilateral; 2. the posterior-upper; 3. the posterior-lower; 4. the slender, rarely exceeding three lines in breadth; 5. the two-bellied or biventral; and 6. the central lobe. The first two belong to the upper or flat hemispherical surface; the next three to the lower or convex hemispherical surface; and the sixth, common to the two hemispheres, is situate on the mesial plane of the upper surface, between the anterior end of the middle line (*raphe*) and the middle or apex of the semilunar fissure.

The tonsils.

The biventral lobe is pointed, and its margin concave; and between this margin and the parts of which the valley consists is placed a group of plates, convex and rounded, named the tonsil or tonsils (*tonsillæ; amygdalæ; the spinal lobule* of Gordon).

The flock.

In the angular hollow between the biventral lobe and the peduncle (*crus*) of the small brain, is the flock, a minute body, of irregular shape. Each flock consists of six or seven plates (*laminæ*), starting directly from the beginning of the peduncle, and with the concave margins directed towards the protuberance.

The pyramid, uvula, and nodule.

The valley is distinguished into three bodies, the *pyramid, uvula,* and *nodulus.* The first is a group of 20 parallel plates, with a triangular apex, bounded behind by the purse-shaped notch, and before by another cluster of plates called the *uvula.* The *uvula,* which is anterior, consists of twelve laminated leaves, is six lines long and four broad, and is smaller than the pyramid, and conical, with its base turned to that body. Lastly, anterior to the *uvula,* and separated from it by a furrow, is the laminar tubercle (*tuberculo laminoso*) or nodule, consisting of about ten thin transverse plates, the smallest in the row.

Central surface.

The second surface of the brain, in situation interior or central, may be named the *figurate* or *symmetrical.* Instead of presenting the uniform eminences and hollows which distinguish the convoluted surface, it is moulded into definite shapes, which correspond with each other, as they are situate on opposite sides of the middle plane,—or the parts of which, when situate on this plane, are exactly symmetrical. The surface formed by these figured objects bounds what are termed the *ventricles* or *cavities* of the brain. They cannot justly be termed cavities any more than the hollows between the convolutions, but ought to be viewed as continuations of the exterior or convoluted surface.

The central or figurate surface of the brain presents the following objects. The central band, beam, or mesolobe, a mass of white cerebral matter, uniting both hemispheres on the mesial plane, with the twainband or vault below; the *hippocampus major* on each side; the anterior pyriform eminence or striated body on each side; the posterior pyriform eminence or optic chamber on each side; the semicircular band on each side; the ergot on each side; the *conarium* on the mesial plane; the bigeminous eminences on the mesial plane; the valve on the mesial plane; and its pillars on each side.

Central band; corpus callosum.

The commutual or dichotomous region of the convoluted surface is terminated below by the upper surface of a white band uniting the two hemispheres. This, which was named by the ancient anatomists the smooth or polished body (*σωμα τιλλωδες, corpus læve*), to distinguish it from surfaces formed by a cutting instrument, appears in the form of white fibrous matter, passing transversely between the hemispheres, and marked by three longitudinal lines, one on the mesial plane, and one on each side. This is the *middle* or *central band* (*mesolobe* of Chaussier). Near its middle is a bundle of gray lines, which may be traced to the central portion of the *hippocampus major.*

Special Anatomy.

The posterior extremity of this body is rounded, and communicates with the chamber named third or middle ventricle. This surface is continued forward, and forms the vault or cieling (*fornix,* Die Zwillingsbinde, *the twainband,* Reil). The names of *callous body* and *vault* are used, as if they were denominations of different bodies. If they are still retained, it ought to be stated that they are names applied to opposite surfaces of the same object.

The triangular vault.

The relations of the posterior end of the middle band are as follow. The handle of a scalpel inserted beneath it is found to be in the middle ventricle, with the vault above, the *conarium* or pineal body, and four eminences of the upper surface of the protuberance (*corpora bigemina*) below, and a part of each optic chamber on each side. The vault or inferior surface of the band has the shape of an isosceles triangle, with the base behind. Before it is incurvated downward as it becomes narrow; and the space between the band and it is occupied by a thin double plate of cerebral matter, separating the two ventricles, and named the diaphanous partition (*septum lucidum*). (s, s, s.) The *fornix* terminates before, in two bodies named *anterior pillars.* (Fig. 3, F, F.)

The hippocampus major.

Superior lateral communication.

The posterior end of the middle band penetrates into the substance of the hemispheres; but the gray chords already noticed, pursuing their lateral course, are immediately enveloped in white plates derived from the sides of the vault, and assuming a cylindrical appearance, form, opposite the cerebral limbs, a body with a free rounded surface, which bends in a curvilinear direction laterally and downwards, and is the great *hippocampus* or cylindroid process. (Chaussier.) In observing this curvilinear course, it rests on and corresponds, but without adhesion, to the upper margin of the cerebral limb as it issues from the optic chamber; and the surfaces of both parts, though kept in apposition by vascular membrane, are free and unadherent. It forms *the great cerebral fissure* of Bichat.

The *hippocampus,* therefore, consists of two parts. The first, which is *the gray indented band* (*le corps godronnée,* Vicq-d'Azyr), is an inner or central portion, as thick as a large crow-quill, gray in colour, indented at the free edge, adhering to the cerebral substance by its opposite margin, and connected with the upper surface of the central band. The outer or second part, which is a broad thin plate of white cerebral matter folded over the gray indented band, as a map is rolled over a cylinder of wood, known under the name of the *tape* or *fringe* of the hippocampus, is connected with the lower surface of the same central band, or the vault (*fornix*) of the brain.

Inferior lateral communication.

At the inferior region the communication is effected by the curvilinear hollow. (Fig. 1, s, s.) This presents, 1*st,* cerebral substance, penetrated by numerous holes of various size, named the *white perforated substance* (*lamina perforata*); 2*dly,* the unconvoluted space; 3*dly,* the long cerebral band termed the *optic tract;* and, 4*thly,* the limb of the brain. This body, with that of the opposite side, is covered by a portion of the convoluted surface, the inner and prominent surface of the medio-inferior or spheno-temporal region.

The convoluted surface, which covers the anterior end and outer margin of the cerebral limb, when everted, presents the thin white body named the *tape* or *fringe* (*tænia*) of the hippocampus; and if the portion of convoluted brain next the curvilinear hollow be raised and everted in the same manner, the anterior end of this object, termed the *foot* (*pes hippocampi*), comes into view. The fringe of the hippocampus forms, in the natural position of the organ, the outer and lower border of the opening; while the limb of the brain, and the outer

Special Anatomy.

and lower surface of the optic chamber, form its inner border.

The striated eminences.

When the central surface is exposed by removing the central band and the vault and cieling of the ventricles, two pyriform eminences, an anterior and posterior, come into view. The anterior is ash-coloured or gray, inclining to wood-brown, with the round convex extremity before, and the small end tapering backwards and outwards, so as to inclose the round end of the posterior eminence. The surface is smooth and convex, consisting of a thin covering of gray cerebral matter. The interior consists of an admixture of white and gray, so as to form alternate streaks,—a circumstance from which these eminences on each side have been named the striated bodies (*corpora striata*). At their anterior mesial extremity are two rounded vertical bodies of white cerebral matter, descending from the anterior end of the vault. These are the anterior pillars, which are thus interposed between the interior front of the striated bodies.

Semicircular band.

The posterior and internal margin of the striated bodies is bounded by a gray, hard eminence, about a line broad, stretching with a sinuous or winding direction from its mesial and anterior to its external lateral and posterior margin. This is the semicircular fillet or band (*tænia semicircularis, centrum semicirculare geminum*). Always firmer than the neighbouring parts, it appears to be the external margin of a gray-coloured stratum or wall of cerebral matter between the anterior and posterior pyriform bodies.

Optic chamber.

Connected before and on the outside to the striated body by means of the double semicircular chord (*centrum semicirculare geminum*, Vieussens), each optic eminence presents four free surfaces—the upper, the inner, the posterior, and the lower. The upper is gently rounded, convex, and white in colour; its limits are not easily defined. The outer margin is bounded by the circular band, which even passes anterior to it, so as to form its boundary in that direction also. Behind, it is less distinctly limited, unless by the appearance of a considerable prominence, named the *posterior tubercle* of the optic couch.

Pineal gland and peduncles.

The inner margin of the upper surface is distinctly marked by a small, sharp, gray line, which, beginning insensibly at the anterior part of the body, becomes more distinct as it extends backwards, and ultimately bends towards the median plane. There it unites with a similar elevated line of the opposite optic eminence; and to the point of union is attached a small conical body with a minute point, of a gray colour, and of a shape like that of the pine-apple. This is the pineal gland (*glandula pinealis, conarium*); and the minute linear eminences which form the inner edge of the upper optic surface have been named *peduncles* of the pineal gland.

Soft commissure and third ventricle.

The inner surface of the optic couch or chamber presents the small portion of soft cerebral matter (*commissura mollis*) which unites it to the similar surface of the opposite body; and the intermediate space between the inner surfaces of these bodies on each side constitutes the third or middle ventricle (*ventriculus tertius*). Its posterior edge, however, is terminated by the cerebral limb of that side; and the lower edge meets that of the opposite one, and is connected to it by a portion of brain which forms the lower part of the middle ventricle, and corresponds on the outside to the *bridge of Tarin* (*pons Tarini*).

Geniculate tubercles.

The posterior surface of the optic chamber is convex and continuous with the unconvoluted space. Its most convex part presents two oblong roundish eminences, separated by a linear depression, which may be traced downwards with an outward curvature, and forwards about five or six lines, in a broad white band, crossing two fluted masses mutually converging behind at an angle. These eminences are the geniculate bodies (*corpus geniculatum externum et internum*), the outer the largest of the two (fig. 1, g, g); the white bands are the optic tracts or origins of the optic nerve, issuing from the geniculate tubercles (o, t); and the fluted converging masses are the limbs of the brain (*crura cerebri*).

Bigeminous eminences.

On the inner or mesial side of the geniculate bodies, and separated only by a linear furrow, are the bigeminous eminences, four orbicular elevations, two above and two below; two on each side of the mesial plane, with an intermediate cruciform furrow. By the ancients, who examined chiefly brute animals, the superior and larger pair were named *nates* (γλουτοι), the inferior *testes* (διδυμοι). These eminences occupy the upper surface of the protuberance, and partly that of the limbs of the brain; and while the eminences are situate between the posterior ends of the optic chambers above, the limbs appear to issue from the centre of these chambers below, and the linear furrow marks the point of junction.

Cerebral valve.

These bigeminal eminences, however, though occupying the superior surface of the protuberance, adhere not everywhere to its substance. (Fig. 3.) The mesial furrow is formed on the upper surface of a thin plate of white cerebral matter, which extends from the level of the pineal peduncles above, to the upper margin of the *cerebellum* below, like a veil, and is named the cerebral valve (*valvula Vieussenii*). The lower surface of this is free for about two or three lines broad; and, though applied to a similar surface on the mesial line of the upper region of the protuberance, does not adhere, but forms a canal with the third ventricle above and the fourth below, named the aqueduct of Sylvius (*iter a tertio ad quartum ventriculum*) (i). While the outer halves, therefore, of the eminences adhere to the matter of the protuberance, the inner are attached to that of the valve. (n, t.)

Pillars of the valve.

The lower or cerebellic margin of the valve is free, and overhangs as it were the fourth or cerebellic ventricle. On each side, however, is a longitudinal rounded body of white matter, which passes from the lower pair of bigeminous eminences (*testes*) to the cerebellum. These are named the pillars of the valve (*columnæ valvulæ Vieussenii, processus a cerebello ad testes*). The fourth or pathetic nerve (*trochlearis*) rises partly from the valve, partly from its lateral pillars, and is seen issuing on the sides of the protuberance not larger than a thread.

The lower surface of the optic chambers presents within the convoluted space the limbs of the brain (*crura cerebri*), two fluted semicylindrical masses, converging backwards, and inclosing by their junction a triangular space, with the apex behind—the *intercrural hollow*. The inner margin of the limbs presents the origin of the third or oculo-muscular nerves (*oculo-motorii*); about half an inch anterior on the intercrural hollow are the lenticular or pisiform bodies (*tubera, v. corpora candicantia*), two hemispherical tubercles of white matter; and immediately anterior is the *hypophysis* or pituitary gland, a broad quadrilateral reddish-gray prominence, with the anterior margin rounded, the posterior concave, inclosed before and on the sides by the converging optic tracts and commissure. (P.)

The limbs are obliquely crossed at their outer anterior end by the broad part of the optic tracts as they descend from the geniculate bodies. Their posterior convergent extremities are lost in the substance of the annular protuberance (*pons Varolii, nodus cerebri*), a convex rounded white body, with transverse *fasciculi* separated by linear furrows. (N.) Connected before with the *crura* or limbs, from which it is separated by transverse sinuous furrows, it is connected on the sides with the cerebellum by short semicylindrical stalks or peduncles (*crura cerebelli*), and

Special Anatomy.

behind with the beginning of the spinal chord (*medulla oblongata*). It is marked on the middle by a longitudinal furrow, in which is placed the basilar artery, the united trunk of the vertebrals. Its convexity corresponds to the concavity of the basilar groove of the occipital bone, on which it rests. This eminence may be regarded as the general central point of the cerebral nervous system, with which all the other parts are connected,—with the cerebral hemispheres by the *crura cerebri*, with the cerebellic hemispheres by the *crura cerebelli*, with the upper internal part of the optic chambers by the bigeminous eminences, and with the spinal chord by the *medulla oblongata*. From its anterior lateral margin the *tergeminal* or fifth nerve arises; from the posterior furrow the *abducent* or sixth nerve; and from the upper anterior margin of the cerebellic peduncle the eighth or lateral facial.

Head of the chord.

Continuous with and behind the protuberance is the beginning or bulb of the spinal chord, a part distinguished on the ground of an obsolete hypothesis by the name of *medulla oblongata*. Thick and prominent, its surface is moulded into six oblong-ovoidal eminences, three on each side of the mesial plane; the *pyriform* or *pyramidal* eminences before, the *restiform* bodies behind, and the *olivary* eminences on each side.

Pyramidal bodies.

The pyriform eminences (*corpora pyramidalia*) are two oblong-oval bodies, broad above, tapering below, separated by a mesial line, and bounded laterally by a furrow separating them from the olivary bodies, occupying the anterior-inferior part of the bulb of the chord, and resting on the lower third of the basilar groove. The mesial line terminates above in the *foramen cæcum* of the posterior furrow of the protuberance. (P.)

Olivary bodies.

The olivary (*corpora ovata*), placed on the outside of the pyramidal bodies, occupying partly the front, partly the side of the bulb, give it a lateral and transverse projection. In the intermediate furrow are the initial filaments of the *hypoglossal* or middle lingual nerve; and in the external furrow and sides those of the *glosso-pharyngeal* and *pneumogastric* nerves. (o, o.)

Restiform bodies and their groove.

The posterior-upper part of the *medulla oblongata* consists of two longitudinal cylindrical bodies, stretching between the cerebellic peduncles above and the spinal chord below. These are the *chordal processes* of Ridley, the *restiform* or rope-like processes of Morgagni, the *pyramidal bodies* of Haller, Malacarne, and Reil, and the *posterior pyramidal bodies* of Ruysch, Prochaska, and Soemmering. Above, where they are connected with the cerebellic peduncles, they are separated by a triangular space with the apex downward, but below by a deep furrow, the *calamus scriptorius* of the ancients, at the bottom of which, when separated, may be observed white chords proceeding from the process of one side, plaited with those of the other. These decussating fibres, which are confined entirely to the mesial margin of the restiform processes, are believed to establish a crossing connection between the right and left sides of the peduncles and the protuberance. The intermediate cavity is named the fourth ventricle. From the inner surface of the restiform process issue several of the initial filaments of the seventh or auditory nerve.

The spinal chord.

The spinal chord or funicular brain is a cylindrical body occupying the interior of the vertebral canal, from the margin of the occipital hole to the first lumbar *vertebra*; large and round on the cervical region, broad on the dorsal, and terminating in a brush-like expansion, denominated the *cauda equina*. On its dorsal surface may be seen a slightly depressed line continued from the middle furrow of the restiform bodies, but becoming faint and indistinct in the region of the back.

The central or figurate surface is smooth, polished, and possesses a degree of closeness of texture which prevents it from being readily abraded. These qualities are ascribed by Reil to a thin pellicle, which he terms *epithelia*. Though there is no proof of the existence of the covering, the term may be used to designate the smooth surface of the organ.

Of the central surface not only does every division mutually communicate, but the central surface of the convoluted communicates with that of the laminated part of the organ. The lateral divisions, named *ventricles*, communicate directly with each other below the vault, the surface of which lies over the *thalami;* both communicate with the third ventricle, which by the Sylvian aqueduct communicates with the fourth; and the posterior part of the lateral ventricle communicates with the digital cavity and inferior recess.

The central surface is covered by a vascular membrane (*plexus choroides*), continued from the *pia mater* of the convoluted surface.

Between the two surfaces now described is placed the proper matter of the brain, white and brown, which in different regions of the organ is differently arranged.

Structure.

The convoluted surface consists of a stratum of gray cerebral matter, arranged in the granular form. When indurated by immersion in alcohol or dilute nitric acid, it breaks with a small conchoidal fracture, occasionally uneven, and with an uneven granular surface, void of lustre and without fibrous arrangement. The only part of the convoluted surface presenting the latter appearance is the unciform band uniting the anterior and posterior lobes. (Fig. 5, v.)

Within the convoluted surface is contained a large quantity of white matter, surrounding the figurate surface and its divisions. The section of this, usually named the oval centre of Vieussenius (*centrum ovale*), shows merely the extent which this occupies in the upper part of the brain, but communicates no information on the intimate structure of the organ.

In intimate organization the brain may be distinguished into four parts; 1*st*, the brain, containing the striated *nucleus;* 2*d*, the cerebellum, containing the moriform body; 3*d*, the head or bulb of the chord, containing the moriform body; and, 4*th*, the annular protuberance as a central point of the whole.

The white fibrous matter of the central band, passing into the hemispheres on each side, diverges like the rods of a fan or the rays of a luminous body, and forms an arrangement denominated by Reil the *radiating crown*, and which may be regarded as the exterior investment of the *striated nucleus*, which constitutes the internal substance of the striated bodies and optic chambers. (Fig. 5, c.) The arrangement of white and gray matter in this part is so peculiar, that within the limits of this sketch it is impossible to convey a distinct idea of it. It may be stated in general that the fibrous matter of the limbs extends from the protuberance through the substance of the *thalamus* and part of the striated body; and while in this manner it maintains a connection between the protuberance and the brain above, by means of the cerebellic peduncles on the sides, and the head of the chord below, it communicates with the cerebellum and spinal chord behind and below. The moriform bodies (*corpora dentata, corpora ciliata, corpora rhomboidea*), which consist of white matter inclosed in a brown capsule, and the *cerebellic* and olivary eminences, are analogous to the striated nucleus of the brain; and the three may be regarded as the respective centres of each. The annular protuberance, consisting internally of transverse fibres closely interwoven with longitudinal ones, is the general or common centre of the three.

Special Anatomy.

The substance of the funicular or vertebral portion consists almost entirely of white fibrous matter, extending longitudinally from the cranial to the sacral extremity, but bending off laterally at the origins of the spinal nerves in the form of arches.

Blood-vessels.

The brain is supplied with blood by the internal carotid arteries and the two vertebral arteries, derived from the subclavian. The former, entering the cranium by the carotic canals, sends a *posterior communicating* branch, inosculating with the principal division of the basilar, and an *anterior communicating*, which joins the vessel of the opposite side. By these communications, the branches of the basilar artery behind, and the carotids before, form an arterial hexagon round the *sella Turcica*, from which arise two anterior vessels (*anteriores cerebri*), distributed to the central band, and two lateral (*mediæ*) or Sylvian arteries, distributed to the perforated spot, the Sylvian fissure and striated nucleus. The vertebral, entering by the occipital hole, send branches to the head of the spinal chord, and uniting to form the basilar, supply the protuberance and cerebellum; then divaricating into posterior cerebral, finally inosculate with the internal carotid to form the arterial hexagon as mentioned. The blood is returned by triangular canals named sinuses, of which there are the superior longitudinal, the inferior longitudinal, the cerebellic (*torcular Herophili*), the lateral, the circular, the superior petrous, the inferior petrous, and the cavernous. The four latter pairs are small sinuses opening into the lateral, where it emerges from the cranium by the temporo-occipital fissure (*foramen lacerum in base cranii posterius*).

§ 2. THE CEREBRAL INVESTMENTS OR MEMBRANES.

The brain is said to be surrounded by three membranous envelopes, the hard membrane (*meninx dura, dura mater*), the web-like membrane (*tunica arachnoidea*), and the soft or thin membrane (*meninx tenuis, pia mater*). To this arrangement, which has been adopted by almost all writers, there is perhaps no great objection. But it simplifies the subject, without misrepresenting, to refer them to two only; one of which, the hard membrane (*meninx dura, μηνιγξ σκληρη, dura mater*), is common to the brain with the inner surface of the scull; the other, the thin membrane (*meninx tenuis, μηνιγξ λεπτη, pia mater*), is proper to the brain only. They may be distinguished, therefore, by the terms *common membrane of the brain* and *proper membrane of the brain*. The arachnoid, again, is a pellucid web common to the cerebral membranes.

The dura mater.

The first of these, the common or hard cerebral membrane (*meninx dura, dura mater*), presents two surfaces, an outer or cranial and an inner or cerebral. The outer surface is irregular, filamentous, and vascular, and the substance of which it consists is distinctly fibrous. The fibres, however, do not follow any uniform direction, but are interwoven irregularly. Maceration causes this membrane to swell and become separated into fibrous threads. It is liberally supplied with blood-vessels, by which it is connected to the inner surface of the scull. No nerves or absorbents have been discovered in it. This outer or cranial surface of the *dura mater* is of the nature of periosteum. Its vessels may be traced into the inner table; it contributes to the formation of the cranial bones in the fœtus, and their nutrition during life.

The inner or cerebral surface of this membrane is smooth, polished, and shining; and, when examined in water, it appears to be formed by a very thin, transparent membrane, through which the cranial or outer surface and the fibrous structure of the hard membrane may be recognised. This pellucid inner membrane, generally termed the *inner lamina*, is the exterior division of the arachnoid membrane.

Vertebral sheath.

The *dura mater* is an extensive membrane, lining not only the interior surface of the scull, but, in a modified form, that of the whole vertebral column. The inner surface of each vertebra has a proper periosteum continuous with the periosteum of the outer surface; and from this issues a quantity of filamentous tissue, which penetrates directly a membranous canal, evidently of fibrous structure (*theca vertebralis*), tough and firm, but more delicate than the cranial *dura mater*. The *dura mater* in its course forms sundry prolongations; for instance, the large crescentic one named the *falx*, the horizontal one termed *tentorium*, and the small crescentic one named *falx minor* or *cerebelli*.

The pia mater.

The thin, soft, or immediate and proper cerebral membrane (*pia mater, meninx tenuis*) presents in like manner two surfaces, a smooth or cranial, which is exterior, and a filamentous or cerebral, which is interior and central.

The outer or smooth surface of the thin membrane (*pia mater*) has a glistening appearance, and is formed by a very thin transparent membrane, exactly similar to that which forms the cerebral surface of the *dura mater*. This surface, named in the ordinary works the web-like membrane (*tunica arachnoidea*), is believed to be a separate membrane from the *pia mater*; but that which forms the inner or cerebral surface of the *dura mater* has a claim equally strong to this distinction.

The inner or cerebral surface of the proper membrane is filamentous, flocculent, and sends out many angular filamentous processes, which, by numerous minute arteries and veins, communicate with the convoluted surface of the brain. These processes (*tomenta*) correspond to the furrows of the convoluted surface in which they are lodged. In detaching the membrane from this part of the brain, numerous vessels are drawn out of its substance; and when the membrane is injected these vessels may be seen distinctly filled, and communicating with the gray matter of the convoluted surface. The veins of this membrane may be traced to the sinuses. Neither nerves nor absorbents have yet been recognised in it. Bichat considers it to contain much cellular tissue, which, however, is denied by Gordon, who could not recognise it. The difference, however, consists merely in name. The *pia mater*, indeed, possesses no cellular tissue like the subcutaneous, the submucous, or the subserous. If, however, a portion of the arachnoid be peeled from it by careful management of the forceps and blowpipe, there is found a quantity of loose filamentous matter uniting this tissue to the fine web of the former. The existence of this tissue between the *pia mater* and arachnoid is further demonstrated by the phenomena of serous infiltration.

Distribution and configuration.

The *pia mater*, or proper membrane of the brain, consists of two parts, an outer, covering the *convoluted* surface of the brain, and an inner or central, entering the cavities formed by the inner, central, or figurate surface, and spread over this surface in the form of what has been termed the vascular or choroid web (*plexus choroides; tela choroidea*).

The continuity of the *pia mater* or exterior division of the proper cerebral membrane, with the choroid plexus or interior division, may be demonstrated in the following manner *First*, The *pia mater* may be traced behind and below the posterior extremity of the middle band (*σωμα τιλλοειδες, corpus callosum*, der balken), where it is continuous with the transverse web called *velum interpositum*, and which may be regarded as the first part of the central division. *Secondly*, From the situation of the *velum interpositum*, it may be traced forwards on both sides of the

Special Anatomy.

mesial plane into the lateral ventricles, spread over the surface of the optic *thalamus* and striated eminence in the form of the vascular web called *choroid plexus*, the right half of which communicates with the left by means of a similar slip of vascular membrane lying beneath the vault (*fornix*), and behind the anterior pillars of that body at the spot termed *foramen Monroianum*. *Thirdly*, It may be traced over the geniculate bodies and *thalami* into the posterior-inferior *cornu*, or sinuosity of the lateral ventricle, where it covers the *great hippocampus*. *Fourthly*, It may be traced at the angle between the *cerebellum* and *medulla oblongata*, or what is named the bottom of the fourth ventricle, where it forms a very minute choroid plexus, seldom noticed by anatomists, but not less distinct, and which may be traced up the fourth ventricle to be connected with the *velum interpositum* in the middle ventricle, and with the lateral portions of the hippocampus on each side. Each of the divisions of the choroid plexus now enumerated may be shown to be mutually connected, and to form parts of one general membrane, which again constitutes the inner or central division of the membrane of which the *pia mater* forms the exterior. Each division of the choroid plexus, in like manner, is connected, by means of minute blood-vessels, to the portion of the figurate cerebral surface on which it rests; and it appears to sustain vessels as the *pia mater* does to the convoluted surface.

In clear water the choroid plexus may be spread out, like the *pia mater*, in the shape of a thin semitransparent web, one surface of which is smooth, the other somewhat flocculent, and the substance of which is traversed by numerous minute vessels. The transparent web, which forms the basis of this membrane, is filamento-vascular; and its smooth free surface, a continuation of the arachnoid membrane, is smooth, polished, and thin, like silver paper.

The arachnoid membrane is common to the *dura mater*, *pia mater*, and choroid plexus. It covers the inner surface of the first membrane, to which it communicates its shining polished appearance, though the want of subjacent filamentous tissue causes it to adhere so firmly, that it cannot be readily demonstrated. After covering the free surface of the *pia mater*, it follows the course of that membrane into the central surface of the brain, and covers the upper or unadherent surface of the several divisions of the choroid plexus. For the demonstration of this fact we must be permitted to refer to Dr Craigie's *Elements of General Anatomy* (chap. xxiii. sect. 1), where the reader will find proofs, which the limits of this sketch do not allow us to adduce here.

From these it results that the arachnoid membrane possesses in arrangement and distribution a great resemblance to the serous membranes. It differs, nevertheless, in its extreme tenuity, in the closeness with which it adheres to the collateral tissues, and in its slight disposition to albuminous exudation. It appears to contain in its structure less filamentous tissue than the pure serous membranes.

The brain is developed from the branches of the internal carotid and vertebral arteries ramified through the vascular membrane (*pia mater*). Formation commences in two orders of vessels mutually directed to each other,—those of the convoluted surface (*pia mater*), and those of the central (*plexus choroides*). The central substance of each part is first deposited; and from these points deposition and moulding proceed to the two circumferences of the organ, The surfaces are therefore formed last; and the vessels gradually shrink as the process approaches to completion.

SECT. II.—THE DISTRIBUTED CHORDS; THE NERVES.

The nerves may be distinguished into classes according to the parts of the brain with which their cerebral ends are connected. On this principle they may be arranged in the following order.

The brain,	Olfactory,	1st pair.
	Optic,	2d pair.
The limbs,	Oculo-muscular,	3d pair.
Protuberance or its parts,	Trochlear (*nervus patheticus*), 4th pair.	
	Trifacial, 5th pair,	Ophthalmic branch. Superior maxillary. Inferior maxillary.
	Abducent,	6th pair.
	Auditory,	7th pair (*portio mollis*).
	Lateral-facial,	8th pair (*portio dura*).
Head of the chord,	Glosso-pharyngeal,	9th pair.
	Pneumogastric,	10th pair (*nervus vogus*,.
	Accessory,	11th pair.
	Hypoglossal,	12th pair.
Spinal chord,	1 Sub-occipital.	
	7 Cervical nerves.	
	12 Dorsal.	
	5 Lumbar.	

The spinal nerves are derived from anterior and posterior roots separated by the *ligamentum denticulatum*, a fibrous notched ligament, covered by arachnoid membrane. According to the researches of Charles Bell and Magendie, the anterior roots furnish motive filaments, and the posterior sensitive. The central connections of most of these nerves have been already mentioned; and their distributed connections have been, and will continue to be, incidentally noticed under the heads of the several organs. It is requisite, however, to notice shortly the relations and general distribution of several nervous chords which perform an important part in the functions of the animal body. These are the pneumogastric, the phrenic, and the great sympathetic or intercostal nerves.

Pneumogastric nerve.

The pneumogastric or *nervus vagus*, the 8th pair of the old nomenclature, the 10th in correct enumeration of the cerebral nerves, rising by various filaments from the furrow between the olivary bodies and the restiform, and from the posterior upper surface of the latter, emerges from the cranium with the jugular vein by the temporo-occipital hole. Here, closely united by filamentous tissue to the hypoglossal, spinal, and glosso-pharyngeal, it descends before the *rectus anticus* and *longus colli* on the outside of the carotid artery, though in the sheath with it, and before the subclavian artery on the right side, on the left before the carotid, enters the chest, where it enlarges in size considerably. (Plate XXXI. v, v.) In the chest it passes behind the *bronchi* in the posterior fold of the *pleura*, and is closely connected to the œsophagus in the shape of a thin cord. Both trunks, on reaching the cardiac end of this tube, pass with it through the diaphragmatic aperture, and are distributed to the stomach. In this course the pneumogastric nerve is divided into five orders of filaments.

1. In the neck it gives branches to the pharynx, and, communicating with the glosso-pharyngeal, forms the pharyngeal plexus, and furnishes a superior laryngeal branch, an external laryngeal, and an internal laryngeal, the latter chiefly to the intrinsic muscles of the larynx.

2. In the chest it sends off branches, which, communicating with those of the superior cervical ganglion, are distributed to the heart.

3. In the chest also it gives off the inferior laryngeal or recurrent nerve (r), which on the right side winding round the subclavian, on the left the arch of the aorta, reascends in the lateral furrow between the windpipe and *œsophagus*, and giving off cardiac, pulmonary, œsophageal, thyroid, and tracheal filaments. is finally distributed to the intrinsic muscles of the laryngeal cartilages. These multiplied connections tend to associate the motions of the glottis with the lungs, and to maintain a general consent between the pharynx, larynx, œsophagus, trachea, lungs, and heart.

Special Anatomy.

4. The pneumogastric trunk forms with the filaments of the inferior cervical ganglion the *anterior pulmonary plexus*, and alone it forms the *posterior pulmonary plexus*, which sends filaments to the lower part of the windpipe, the *bronchi*, the pulmonary artery and veins, and the *œsophagus*.

5. After passing the diaphragmatic aperture, the right pneumogastric trunk forms at the cardiac orifice of the stomach a plexus, from which filaments proceed to the *pylorus*, the gastro-hepatic artery, the right cœliac ganglion, the duodenum, the pancreas, the gall-bladder, and the liver, where it communicates freely with the cœliac ganglions. The pneumogastric of the left side is distributed chiefly to the pylorus and its arteries, and communicates freely with those of the right.

The phrenic nerve. The phrenic or diaphragmatic nerve, connected above with filaments of the pneumogastric, hypoglossal, second and third cervical nerves, and some branches of the brachial plexus, and occasionally with those of the great sympathetic, descends on the anterior and lateral part of the neck, between the *rectus anticus* and *scalenus anticus*, and enters the chest between the subclavian artery and vein. The right passes down on the surface of the right lung, beneath the pleura (φ, φ, Plate XXXI.); the left over the pericardium; and both are distributed chiefly to the diaphragm.

The great sympathetic or splanchnic nerve. The great sympathetic is much more complicated than either of these nerves. It cannot be said to originate from one part more than from another. Though connected with the brain by means of a communicating filament of the sixth pair, it certainly does not arise from that nerve: nor can it be said to arise from the spinal nerves, though connected with them on each side of the dorsal vertebræ. It appears more rational to regard it as a general and extensive network of nervous filaments, which establish a communication between different important organs. Connected above with three ganglions of the neck, the *superior*, *inferior*, and *middle cervical*, and by minute filaments with the lateral-facial, or eighth cerebral, pneumogastric, and glosso-pharyngeal, with which it contributes to form the pharyngeal plexus, it sends off the *nervi molles* or *superficial cardiac nerve*. Below the inferior cervical ganglion, generally regarded as a cardiac, the trunk enlarges, and furnishes filaments to the pulmonary and cardiac plexus, the former divided into right or anterior and left or posterior, and the latter into superior and inferior. About the seventh dorsal *vertebra*, after being connected with all the intercostal nerves and inferior thoracic ganglions, it forms the *splanchnic*, which, though only the abdominal part of the great sympathetic, may be regarded as a separate nerve. The constituent filaments of this nerve, after being united into two ganglions, the cœliac or semilunar, are resolved into plexiform arrangements, which surround all the principal arteries, and with them are lost in the substance of the organs. Thus the cœliac artery is inclosed by the cœliac plexus; and each of its divisions, the coronary or proper gastric and the gastro-hepatic and gastro-splenic, are inclosed in similar plexiform networks. In the same manner, the superior mesenteric, inferior mesenteric, and renal arteries, have each an appropriate plexus; and those of the colon, bladder, and uterus have small plexiform arrangements, which constitute parts of the same general system. In short, the great sympathetic or intercostal forms an independent nervous system of its own, and though not derived from the dorsal nerves, is intimately connected with them; and its distribution to the organs of digestion, of circulation, respiration, and secretion, is connected chiefly with the associated actions of these organs.

Our limits do not, however, admit of details; and the reader who wishes to understand the minute anatomical relations of these chords, will find the most accurate information in the fourth volume of the treatise of Soemmering (*De Corporis Humani Fabrica*, Trajecti ad Mœnum 1798); in the third of the Descriptive System of Bichat; and in the magnificent illustrations of Walter (*Tabulæ Nervorum Thoracis et Abdominis*, fol. Berolini, 1783) and Scarpa (*Tabulæ Neurologicæ*, fol. Ticini, 1794).

PART II.

ANATOMY OF THE ORGANS PERTAINING TO THE ENTROPHIC OR NUTRITIVE FUNCTIONS.

The growth of the animal body is effected, and its size and strength maintained, by a class of organs which may be named the *Entrophic* or *Nutritive*. These organs agree in the possession of certain common characters, by which they are distinguished from those of the functions of Relation.

The *first* common character is the want of symmetry in arrangement and harmony in action. Instead of being arranged on the median line, or with similar parts on each of its sides, the organ, or part of the organ, which is on one side, bears no resemblance to that which is on the other. Even in the case of the lungs, though there is a general resemblance, the left differs from the right not only in size and shape, but in the number of its lobes.

It must not be understood, nevertheless, that the organs of this class are altogether void of symmetrical figure. A plane may be made to divide the stomach even into similar halves, so as to leave on each side similar parts of the *cardia*, of the *pylorus;* and of the intermediate parts. This plane, however, corresponds not with the mesial plane, but passes transversely from left to right. Nearly the same rule is applicable to other organs.

The *second* general character of the entrophic organs is, that in action they are not under the influence of the will. The contractions of the muscular tissue of the stomach, and the secretion of its mucous surface, the peristaltic motion of the intestinal tube, the beats of the heart, and the action of the liver, are equally independent of volition. This character Bichat attempted in every instance to trace to independence on the influence of the brain and the cerebral nerves. In one sense this is a truism, in so far as it merely implies that the organs of the entrophic functions do not belong to those of relation. In another sense it is a gratuitous, if not a hypothetical assumption. Though the brain is evidently very intimately associated with the organs of the animal functions, it is not yet determined that it is entirely unconnected with those of the entrophic order. Serious lesion or injury of the brain or the protuberance operates as forcibly on the action of the heart as on that of the muscles of the extremities. On the whole, the safest mode of defining this character is merely to state the independence of the entrophic organs on the will.

Several of the organs of the entrophic function are nevertheless in some degree under the influence of the will. The lungs, for example, by being dilated only by the dilating agents of the chest, are within certain limits under the voluntary power. To this, however, a limit is fixed. Though inspiration or expiration may be effected at the will of the individual, or suspended for a little, very soon the accomplishment of these actions is no longer arbitrary. In like manner, though the bladder is evacuated by the voluntary effort of the individual, the stimulus by which the action is induced is involuntary altogether.

A *third* anatomical character common to the entrophic organs is, that all of them are situate in the interior of the

trunk, protected by those of the locomotive system; and that they are lined on one side by mucous membrane, continuous with the external integuments. By means of this arrangement, which is necessarily allied with their property of converting foreign into proper matter, all the entrophic organs, with the exception of the heart, communicate with the surface of the body.

A *fourth* anatomical character common to these organs is, that though continuous by their mucous investment with the outer surface of the body, their opposite, placed on the outside of the serous membranes, forms shut cavities, not communicating, unless in one instance—the peritoneal end of the oviduct in the female—with the external surface. Whatever be the intermediate substance, these organs are placed between the mucous and serous membranes.

The entrophic organs may be distinguished into two orders, according to the degree of the process performed by each. The nutritive function consists of two subordinate functions, the *limitrophic* or alimentary, and the *hæmatrophic* or circulatory; the first the preparation of the materials destined to be employed in nutrition; the second the distribution of these, after preparation, to the different regions and organs of the system. The organs by which the first process is accomplished constitute the first order; those by which the second is effected constitute the second order.

CHAP. I.—THE LIMITROPHIC ORGANS.

The limitrophic organs consist of two divisions; those for digestion of the food, or the chylopoietic, and those for absorption of its nutritious part. The former is effected in successive processes in the divisions of the alimentary canal, a tubular musculo-membranous apparatus, extending from the mouth to the anus. The second is accomplished by an assemblage of minute valvular tubes, the lacteals, terminating in the thoracic duct.

SECT. I.—THE ORGANS OF DIGESTION; THE CHYLOPOIETIC ORGANS.

The organs of mastication have been described already in the fourth section of the second chapter of Part First.

The pharynx.

The *pharynx*, placed on the median line, symmetrical and regular, occupying the upper part of the neck, makes a close approach to the organs of relation, and marks the transition from these to those of the entrophic function. Attached above to the cuneiform process of the occipital bone, behind to the cervical vertebræ, and with the nostrils, mouth, and larynx before, it forms an irregular vaulted apartment about four inches long and two broad at its widest part, and contracting below, where it is continuous with the *œsophagus*. Besides the opening into this tube, the *pharynx* presents six apertures; the pharyngeal apertures of the nostrils, the pharyngeal orifice of the mouth, the upper end of the larynx, and the pharyngeal apertures of the Eustachian tube.

It consists of a mucous membrane stretched over loose filamentous tissue inclosed by three muscles, the superior, inferior, and middle *constrictor*, and attached to the cuneiform process, the cervical vertebræ, and the lateral regions of the neck, by filamentous tissue.

By the superior laryngeal, the pharyngeal, the thyroid, the lingual, and palatine arteries, it receives blood, which is returned by a still greater number of veins to the external and internal jugular trunks. The nerves of the pharynx come from the glosso-pharyngeal, the hypoglossal, the pneumogastric, and the great sympathetic.

The œsophagus.

The *œsophagus* (*gula*) is a cylindrical musculo-membranous tube, communicating above with the pharynx, and below with the stomach. Placed above between the cervical vertebræ behind and the windpipe before, at the lower end of the larynx it inclines to the left, returns to the median line at the sternum, bends again to the left at the bifurcation of the trachea, and continues on the left side of the line, passing the aperture of the diaphragm, near the ninth dorsal *vertebra*, to its junction with the stomach. With the vertebral column behind, at its first inclination it covers the *longus colli* in the chest, crosses the *vena azygos* above, and covers the thoracic duct in the middle, and the aorta below. With the jugular veins and carotids on each side in the neck, below it has the *trachea* on the right, and the recurrent nerve and common carotid on the left; and in the chest it has the aorta on the left and behind. (Plate XXIX. fig. 2, c.)

Lined on the inside by a follicular mucous membrane which assumes longitudinal folds (*plicæ*), the œsophagus consists of two ranges of muscular fibres, the one transverse, the other longitudinal. The first are most distinct at the pharyngeal end. The second form a manifest thick layer through the whole extent of the tube. Externally is a quantity of filamentous tissue, connecting the tube to that of the mediastinum and adjoining parts.

The œsophagus is supplied with blood from the inferior thyroid, thymic, laryngeal, pharyngeal; the aorta by proper œsophageal arteries, the superior intercostals and bronchials, the pericardial, mediastinal, diaphragmatics, and even the coronary of the stomach. The blood is returned by veins equally numerous. The œsophageal nerves proceed from three different sources. Above, it receives filaments from the glosso-pharyngeal and pneumogastric, in the middle from the latter, and below from the pneumogastric and the great sympathetic.

The stomach.

The stomach (*ventriculus*) is a large pyriform musculo-membranous sac, incurvated on itself (Plate XXIX. fig. 2, and Plate XXXVI. fig. 4), situate in the epigastric and left hypochondriac regions, communicating above with the œsophagus, and below with the duodenum. Bounded above by the diaphragm, and the liver, which covers it, it has the spleen attached to its left great extremity, the transverse arch of the colon to the inferior large arch; and its posterior surface corresponds to the duodenum, pancreas, mesocolon, and large abdominal vessels.

The pyriform sac of the stomach is distinguished into a large end or sac (*fundus*), and a small extremity named the *pyloric*; while a particular incurvation of its direction gives it a large inferior arch (*arcus major*), and a small superior arch (*arcus minor*). At the left extremity of the latter is the *cardia*, the orifice by which the œsophagus enters the stomach (*osteum œsophageum*); and from this round the *fundus* is the large arch. A vertical plane drawn from the *cardia* divides the stomach into two portions,—the *cardiac* (*fundus*, *saccus cæcus*), and *pyloric*, terminating in an annular contracted opening, about an inch broad (*pylorus*, *ostium duodenale sive pyloricum*). Between the two arches is the *superior-anterior* surface, covered partly by the left lobe of the liver, partly by the left *rectus* and hypochondre, and the *inferior-posterior* surface behind.

Structure.

The stomach consists of peritoneum externally, mucous membrane internally, and an intermediate muscular layer with filamentous tissue.

The peritoneal covering is arranged in a peculiar manner. The anterior fold, meeting the posterior at the small arch, joins it, and forms a membranous production (*omentum gastro-hepaticum*), connecting the organ to the inferior surface of the liver, where they again separate to invest the upper and lower divisions of that organ. These folds, meeting in like manner along the large arch, where they form similar duplicatures, are again separated to in-

Special Anatomy.

close the spleen at the large end, and the colon along the lower division. In the triangular spaces formed by these duplicatures the gastric blood-vessels are lodged.

The mucous membrane, void of epidermis, is covered with minute piles (*villi*) from the cardiac, where they commence at the fringed termination of the œsophageal epidermis, to the pyloric, where they are continuous with those of the duodenum. It is further puckered into wrinkles (*rugæ*) or folds (*plicæ*), intersecting each other irregularly, and inclosing irregular quadrilateral spaces,—an effect produced by the contraction of the muscular coat, and connected with the great extent of the gastric villous membrane. In this also are contained follicular glands, especially at the pyloric end and along the two curvatures.

The muscular coat consists of two ranges of fibres, one longitudinal, following the great diameter from the *cardia* to the pyloric end; the other circular internal, inclosing the circumference of the organ, and most distinct when the organ is empty. On the latter depends the contracted incurvation of the stomach between the cardiac and pyloric divisions. (Plate XXXVI. fig. 4.) Besides these, there are on the left side of the cardia muscular slips expanded on the two surfaces.

Gastric vascular system.

The stomach derives its blood from the cœliac artery, the branches of which are arranged in a peculiar and beautiful manner. The cœliac divides into three vessels; one gastric proper, the *coronary;* one common to it and the liver, the *gastro-hepatic;* and one common to it and the spleen, the *gastro-splenic.* The first, the coronary, is distributed to the cardiac end, and, lodged in the peritoneal fold of the small arch, proceeds towards the *pylorus,* distributing branches before and behind. The second, after sending a large vessel to the liver, the hepatic, sends a small one (*arteria pylorica*), from the pyloric end, towards the gastric, by the superior peritoneal fold, to meet the terminal branches of the coronary; and a large one (*gastro-epiploica dextra*), by that of the large curvature, to meet the terminal branches of the left *gastro-epiploic.* The third or spleno-gastric artery, after transmitting a large vessel to the spleen, and various small vessels (*vasa brevia*) to the large *fundus,* sends a large vessel (*gastro-epiploica sinistra*), in the peritoneal fold of the large arch, to inosculate with the terminal branches of the right gastro-epiploic. The stomach is in this manner embraced, as it were, by arterial canals above and below. It is further remarkable, that while only one proper gastric artery, of inconsiderable size and limited distribution, proceeds from the cœliac trunk, the gastro-hepatic and gastro-splenic, each not much less than the cœliac itself, send their largest branches to the stomach, and proceeding from opposite ends of that organ, inclose it, meeting by inosculation in the middle of its great and small curvatures. From the capillaries at the *fundus,* chiefly the *vasa brevia,* the gastric fluid appears to be secreted. The blood, returned by corresponding veins, is poured into the portal.

The stomach receives nerves from the pneumogastric and the great sympathetic. In the stomach the alimentary mass is converted into the pulp named chyme.

The duodenum.

The *duodenum* (*ventriculus succenturiatus*), about twelve inches long in the human subject, is distinguished by being the most fixed part of the tube in situation. Placed on the vertebral column, and on each side in the cavity of the mesocolon, behind the stomach, and concealed by that organ, it is bounded above by the liver and gall-bladder, below by the pancreas and lower part of the mesocolon, and maintains the communication with the pyloric end of the stomach and the ileum. The duodenum is divided by two curvatures into three portions. The first, which is covered by peritoneum, extending from the pylorus to the site of the neck of the gall-bladder, horizontally backwards and a little to the right, descends about two inches almost perpendicularly. With this the second portion, forming an angle, ascends obliquely to the left, and terminates opposite the third lumbar *vertebra.* The third, forming an angle rather more than right, extends about two or three inches, and terminates at the peritoneal ring, about one inch on the left of the spine, where the ileum commences. The aperture of the common biliary duct, inclosed in a nipple-like process, and the pancreatic, are in the first portion. These curvatures are firmly connected by filamentous tissue; and the bowel retains them even after removal from the body.

The duodenum, void of peritoneal covering, consists externally of cellular tissue, inclosing a range of circular muscular fibres, and lined by villo-mucous membrane, arranged in numerous folds, or *valvulæ conniventes.* The duodenal arteries are derived chiefly from the gastro-hepatic, and are very generally pyloric twigs. This membrane is provided with follicles, first well described by Brunner.

In the duodenum, by admixture of the biliary and pancreatic fluids with the chyme, the latter is prepared for the separation of chyle, which, though more proper to the ileum, is begun nevertheless in this bowel. The comparative immobility of the bowel is requisite, both in consequence of the admixture now mentioned, and also of the fixed situation of the two glands by which the fluids are supplied.

The ileum.

The *ileum* (ειλεον) or small intestine (*intestinum tenue*), the longest part of the intestinal tube, extending generally from 28 to 30 feet, commences at the annular process above mentioned, and extends to the head of the colon, in which it opens in the right iliac region. It consists of a cylindrical musculo-membranous tube, surrounded by peritoneum, the two folds of which, meeting behind, attach it for the space of three or four inches to the vertebral column, and are again reflected laterally, as described in the first book of this treatise. This attaching membrane is named the mesentery. The great length of the tube, with the small extent of the mesentery, causes it to hang suspended in numerous turns or convolutions. By the ancients this intestine was distinguished into two parts, *jejunum* or the empty, and the *ileum* proper; and Winslow idly undertook to fix the limits of this division by referring the two upper thirds to the former, and the two lower to the latter. This distinction, however, for which there is no anatomical foundation, must be rejected as at once arbitrary and useless.

The muscular tunic consists of circular fibres entirely.

Structure.

The villo-mucous membrane presents numerous *valvulæ conniventes,* which increase its surface to at least double that of its proper area. These duplicatures are most numerous in the upper part of the tube, and diminish as they descend.

The villi

The mucous surface of the ileum is peculiar in presenting the piles or villosities in their most perfect form. When a portion of ileum is inverted, inflated, and immersed in pure water, an infinite number of minute processes are seen waving amidst the fluid; but a powerful glass does not enable the observer to determine whether they are round or flat, solid or hollow, obtuse or pointed. Of their shape and structure various accounts are given.

They were first represented, in 1721, by Helvetius, as cylindrical prominences in quadrupeds, but conical in the human subject. According to the microscopical observations of Lieberkuhn, each *villus* receives a minute lacteal tube, arterial branches, a vein, and a nerve; and in each the lacteal is expanded into a minute sac or bladder (*ampullula, vesicula*) like an egg, in the apex of which may be seen by the microscope a minute opening

Special Anatomy. The villi. On this sac the arterial branches are ramified to great delicacy, and terminate in minute veins, which then unite into one trunk; while its inner surface he represents as spongy and cellular. The space between the *villi*, which do not touch each other, he further represents to be occupied by the open orifices of follicles, so numerous that he counted eighty of them where were eighteen *villi;* and both, he asserts, are covered by a thin but tenacious membrane similar to epidermis.

Hewson, while he admits in each villus the ramification of minute arteries and veins, denies the saccular expansion, and infers that the lacteals are ramified in the same manner as the blood-vessels, and that the whole constitute a broad flat body, the spongy appearance of which he ascribes to the mutual ramification of the latter. With this in general Cruikshank agrees; while Sheldon, who found the *villi* not only round and cylindrical as Hewson, but bulbous as Lieberkuhn, and even sabre-shaped, rather confirms the statements of that anatomist. Mascagni and Soemmering, agreeing in the general fact of vascular and lacteal structure, seem to represent the shape of the *villus* as that of a mushroom, consisting of a stalk and a *pileus.*

Some of these discordant statements Hedwig attempts with equal ingenuity and industry to reconcile. The differences in shape he refers to differences in the animals examined; and in one class finds them cylindrical (*e. g.* in man and the horse); in another conical (the dog); in a third club-shaped (the pheasant); and in a fourth pointed or pyramidal (*e. g.* the mouse). The interior structure he also represents as spongy in all the animals which he examined; and invariably also he found at the apex the orifice of the duct, which, after the example of Lieberkuhn, he conceives constitutes the *ampullula.*

These conclusions are not exactly confirmed by the researches of Rudolphi, who examined the *villi* in man and a considerable number of animals. This anatomist never found the orifice seen by Hedwig, notwithstanding every care taken to distinguish it. He maintains that the *villi* are not alike in all parts of the intestinal canal of the same animal, as represented by Hedwig, but may be cylindrical in one part, club-shaped in another, and acuminated in a third. Admitting their vascular structure, which he thinks may be demonstrated, he regards the ampullular expansion as doubtful, and denies its cellular arrangement.

About the same time Bleuland, who had previously examined the intestinal mucous membrane, after successful injection of its capillaries, undertook to revive the leading circumstances of the description of Lieberkuhn. By examining microscopically well-injected portions of intestine, he shows that the *villi* are composed of a system of very minute arterial and venous capillaries, inclosing a lacteal, which constitutes the *ampulla*, and in the interior of which a certain order of these capillaries terminates. He also revives the statement of the absorbing orifice at the extremity of each *villus.*

According to the observations of Beclard, the intestinal *villi* appear neither conical, nor cylindrical, nor tubular, nor expanded at top, as described by several authors, but in the shape of leaflets or minute plates, so closely set that they form an abundant tufted pile. Their shape varies according to the manner in which they are examined, and according to the part. Those of the pyloric half of the stomach and *duodenum* are broader than long, and form minute plates; those of the *jejunum* are long and narrow, constituting piles; at the end of the *ileum* they become laminar, and in the colon are scarcely prominent. They are semitranslucent; their surface is smooth; and neither openings at their surface, in their cavity, or in their interior, nor vascular structure can be recognised.

Special Anatomy. Peyerian glands. The villo-mucous membrane of the *ileum* is provided with mucous follicles of two orders, the *glandulæ solitariæ* and the *glandulæ agminatæ;* the former, like granules, disseminated over the attached surface of the mucous membrane; the latter clustered in bodies at the anterior exterior part. They partake of the general characters of follicular structure.

The *ileum* is liberally supplied with blood by the superior mesenteric artery, the arrangement and distribution of which may be understood from fig. 4, Plate XXIX.

The nerves are derived from the solar *plexus.*

The colon. The colon, or large intestine (*intestinum crassum*), beginning in the right iliac region, extends round the folds of the abdominal cavity, inclosing the *ileum*, to the left iliac and pelvic, where it terminates in the *rectum.* Its length is from six to seven feet. The beginning (*caput cæcum*) is a round obtuse bowel, with a minute tubular process, varying in length, named the vermiform. The lower end of the ileum is inserted into the beginning of the colon laterally; and to the part below the insertion the name of *cæcum* or blind gut is restricted. From the *cæcum* the colon descends to the right hypochondre (*colon dextrum*), where it is connected at the hepatic flexure to the liver by the hepato-colic ligament, two folds of peritoneum, with intermediate filamentous tissue; between the right or hepatic flexure and the left or splenic it is distinguished as the transverse arch (*colon transversum*), attached to the large arch of the stomach by the gastro-colic margin of the *omentum;* an angular bend in the left hypochondre forms the splenic flexure; and, finally, after making a long sinuous alternating bend in the left iliac and pelvic regions, named the sigmoid flexure, it terminates in a portion comparatively straight (*το ευθυ, rectum*), and following only the antero-posterior incurvation of the inner surface of the sacrum, on which it is placed.

The colon is about two inches in diameter at an average.

The appearance of this intestine is intimately connected with its structure. Inclosed in peritoneum, by the posterior junction of which it is connected to the adjoining organs, it consists of a layer of circular fibres, intersected by three bands of longitudinal fibres. Both are asserted to be muscular; but perhaps the latter are more of the nature of aponeurosis, to give support and resistance to the action of the former. Whatever be their nature, however, they give the colon the appearance of being divided into transverse cells, separated by superficial partitions.

The mucous membrane of the colon possesses the villous character in the cæcum and right part, but loses it towards the lower part of the intestine. It is formed into large transverse folds or duplicatures, which separate the internal cells or compartments of the bowel.

The ileo-cæcal valve. At the insertion of the ileum into the colon the mucous membrane of each is prolonged with the submucous tissue, and they mutually meet in two crescentic processes, one superior, small (*plica superior, labium superius*), the other inferior, large (*plica inferior, labium inferius*), and approaching, by its greater prolongation, the paraboloid shape. The ileal side of both folds is concave, the cæcal or colic convex; and between their free margins, which are rounded, is an intermediate fissure, maintaining the communication between the two intestines. This arrangement, which is named the ileo-cæcal valve (*valvula Bauhini*, from its supposed discoverer), is supposed to allow the transit of alimentary and excremental matter from the ileum to the colon, but not in the converse direction.

The organization of the rectum is the same as that of the colon generally; but it is uncovered by peritoneum behind. Its lower extremity is surrounded by two circular ranges of muscular fibres, named the internal and ex-

Special Anatomy.

ternal sphincters. The lower fibres of the *levator ani* are inserted into its sides.

Vascular system.

The cæcum and right and transverse portions of the colon are supplied with blood from the superior mesenteric, by means of the *colic* arteries. The left iliac or sigmoid flexure receives vessels from the inferior mesenteric. The splenic part is supplied by vessels derived from the great anastomotic communication between the superior and inferior mesenterics. (Plate XXIX. fig. 4.) The *rectum* is copiously supplied with blood from three different sources. The first is the termination of the inferior mesenteric, which is contained between the folds of the *mesorectum*, under the name of *superior hemorrhoidal.* The second is the *middle hemorrhoidal*, or proper artery, derived from the hypogastric or posterior iliac. The third is the *internal pudic*, the lower or perineal branch of which supplies the sphincter with several branches on each side, distinguished by the name of *inferior hemorrhoidal* arteries.

The nerves are derived partly from the hypogastric plexus, partly from the sacral branches.

The rectum, like the pharynx, placed between the two classes of organs, entrophic and animal, belongs in some degree to both. As the termination of the alimentary canal, it belongs to the former; but by its sphincters and *levator* it pertains to the latter.

The appendages of the alimentary canal are two glands, the liver and pancreas, and a cellulo-vascular organ, the spleen

The liver.

The liver (*hepar, jecur*) is a large glandular organ, weighing from two to three pounds, situate in the right hypochondriac and epigastric regions, with the diaphragm above, and the hepatic flexure of the colon and the stomach below. It has a convex upper surface, a concave lower one, a posterior obtuse margin attached to the diaphragm by cellular tissue, and an anterior inferior acute one which is free. The lower surface is distinguished into right and left lobes by a middle pit (*sulcus umbilicalis, v. horizontalis*), in which the round ligament, the residue of the umbilical vein, is contained, and which is occasionally a canal by an arch of hepatic substance. The inferior surface of the left lobe is divided into anterior and posterior parts by a transverse furrow (*sulcus transversus, fossa transversa*), in which the trunk of the hepatic arteries, and the portal vein, and the hepatic ends of the biliary ducts, are contained. The margins of this furrow, which are elevated in the lower animals, were named gates by the ancients (*πυλαι, portæ*), from an erroneous theory. The posterior, which is most prominent, is distinguished by the name of small lobe of Spigelius (*lobulus Spigelii*). The other distinctions of this surface into *lobulus quadratus* and *lobulus caudatus* are immaterial. Between the anterior portal eminence and the umbilical *fossa* is an oval depression (*fovea cystica*), containing the gall bladder.

The liver is invested by peritoneum, the folds of which connect it to the neighbouring organs, and retain it in its place. Of these, the most important are the broad and coronary above, the lower or falciform below, and the gastro-hepatic duplicature between the liver and stomach. This forms the investment named *capsule* of Glisson, in which the portal veins are inclosed.

Structure and organization.

The structure of the liver is glandular. Two classes of vessels and a system of tubes are distributed in it; one ramifying into branches and minute tubes, the hepatic artery and portal vein; another, the hepatic veins, converging to a trunk, the *vena cava hepatica;* the third, the *pori biliarii*, converging into ducts terminating in the hepatic duct. From the researches of numerous anatomists, it appears that the hepatic artery, which is derived from the cœliac, and the portal vein, formed from the veins of the stomach, intestines, spleen, and pancreas, terminate in minute vessels mutually communicating. It appears further, that these capillaries communicate with those of the hepatic veins, and even the origins of the biliary pores; and Soemmering especially infers, that every hepatic *acinus* consists of hepatic artery, portal vein, hepatic vein, bile-pore, and lymphatic. From this, however, it does not altogether result that bile is secreted from the hepatic arterial blood. Each *acinus* may require a minute artery for nutrition, a portal venule for furnishing the materials of secretion, a duct for receiving the secreted product, and a vein for returning the residual blood.

The hepatic duct unites at an angle with the cystic, and forming the common duct, terminates in the duodenum. The gall bladder, which is a pyriform bag, with the *fundus* below and before, and a neck above and behind, acts as a receptacle for the bile when it is not required in the duodenum. The *fundus*, placed between the concave surface of the liver above, and the convex one of the pyloric division of the stomach below, may be compressed by that part of the organ when distended, so as to expel the bile from its cavity.

The pancreas.

The *pancreas* is a flat, oblong, glandular body, measuring from five to six inches in length, and weighing from three to five ounces, contained in the posterior epiploic cavity below the duodenum. It consists of lobules similar to those of the salivary glands. It has a proper artery, from which the pancreatic fluid, very similar to the salivary, is secreted, and conveyed into a small duct. The residual blood is conveyed by a proper vein to the portal.

The spleen.

The spleen (*lien*) is an oblong hemispheroidal organ, of a deep blue venous blood colour, varying in weight from 6 to 12 or 15 ounces, placed in the left hypochondre, between the *fundus* of the stomach and the left side of the diaphragm, with a plane surface applied to the former, and a convex to the latter part. The spleen is covered by peritoneum, which, doubling before, forms along the middle of the organ a gastro-splenic *omentum*, by which it is attached to the stomach. It is generally connected to the colon by a short peritoneal slip.

The intimate structure of the spleen is peculiar. It consists of a number of minute communicating compartments, separated by *septa*, with white granules intermixed These cells contain dark-coloured blood; and the organ is indeed more abundantly filled with this fluid than any other in the body. These cells appear to be of the nature of erectile vessels. The splenic artery is very large in proportion to the organ, and apparently communicates by minute terminations with veins, in which the blood is occasionally accumulated.

The principal use of the spleen appears to be, that it serves as a receptacle for a large quantity of blood, which accumulates in the splenic vessels, or flows into those of the stomach, as the latter organ requires. When the stomach is empty, it shrinks; and its blood-vessels, folded on themselves, neither require nor transmit so much of this fluid as they do when the organ is distended. In the latter case the vessels are stretched, their canals are rectified, and the blood flows freely through them. At this period the additional supply seems chiefly to be derived from the spleen. The splenic vessels also appear to contribute chiefly to the secretion of the gastric fluid, which is most abundant at the fundus of the organ.

SECT. II.—THE CHYLOPHOROUS VESSELS.

On the lacteals or intestinal lymphatics it is superfluous to add any thing to what is stated in Book I.

These vessels arise from the villous surface of the ileum, and proceeding between the folds of the mesentery, unite at the vertebral margin of that membranous duplicature, somewhere between the third lumbar vertebra and the aor-

Special Anatomy.

tic opening of the diaphragm. Here they terminate in a jointed irregular tube situate behind the aorta, and which, passing through the aortic opening of the diaphragm, proceeds through the chest between the artery and *vena azygos*, as high as the sixth, fifth, or fourth dorsal vertebra. Here it inclines to the left, and, passing behind the aortic arch and the left subclavian artery, winds to the left of the latter vessel, and, before the *longus colli*, ascends as high as the seventh or sixth cervical vertebra, where it terminates in the angle between the internal jugular and subclavian veins, in the trunk of these vessels. This is the *thoracic duct*. A similar vessel, though smaller, is found on the right side.

CHAP. II.—THE HEMATROPHIC ORGANS.

The organs of the hematrophic or circulating function consist of the heart as a central propelling agent, and of arteries and veins as distributing and reducent channels. The hematrophic organs may be distinguished into three orders; *first*, those of the general or nutritive circulating system; *secondly*, those of the aerating circulating system; and, *thirdly*, those of the secreting system. Of these the heart is the central agent; but in the mammalia and man it consists of two divisions, one pertaining to the general arterial, the other to the pulmonary or aerating system.

SECT. I.—THE ORGANS OF NUTRITIVE CIRCULATION.

§ 1. THE HEART AND HEART-PURSE.

The heart is a conical muscular organ, containing four communicating chambers, inclosed in a membranous sac, and situate in the anterior middle region of the thorax.

The pericardium. The inclosing sac, named heart-purse, or capsule of the heart (*pericardium*), consists of two portions or layers, an outer or proper capsular, and an inner or lining division. The outer or proper capsular part of the pericardium possesses the characters of a fibrous membrane, of some density and considerable strength. When washed, its colour is gray or grayish-white, and it appears to consist of minute fibrous threads, arranged without definite order. These fibres are most distinct at its lower margin, where it is connected to the circumference of the tendinous part of the diaphragm. In the young subject it is generally thin and translucent; in adult age or advanced life it is thicker and more opaque. This part of the pericardium is a mere investing membrane, which bounds the region containing the heart, but which extends no further. It embraces the origins of the large vessels above, adheres to the margins of the tendinous centre below, and is on each side connected with the pleura.

The inner surface of the pericardium has the appearance of a transparent or serous membrane, through which the fibres of the outer or capsular part may be seen, and which has the usual glistening aspect of such membranes. It is difficult, however, to insulate it from the outer layer, unless by boiling, when it may be peeled off in minute shreds.

Like the transparent membranes, this inner layer has neither beginning nor end, neither origin nor termination. After lining the inner surface of the proper capsule, it may be traced from the angle at which this capsule adheres to the large arteries and veins, over the auricles, and finally, over the outer surface of the ventricles to the apex of the heart.

In this course it preserves the characters of a thin transparent membrane, with a free surface, smooth, glistening, and moistened by a watery fluid; and an attached one, adhering on the one hand to the inner surface of the capsule, and on the other to the outer surface of the heart by means of fine filamentous tissue.

Injection shows that the pericardium consists chiefly of minute arteries and veins. The former are derived from the thymic, phrenic, bronchial, œsophageal, and coronaries of the heart. The substance of the capsular part is probably a modification of the white fibrous system. Nerves have not been traced to any part of this membrane; nor is it ascertained that it contains lymphatics.

Of a general conical shape, the heart (*cor*) is situate obliquely beneath and behind the sternum, with the base (*basis*) above and towards the right, and the tip (*apex*) pointing downwards, forwards, and towards the left. The axis of the cardiac cone lies at once obliquely from right to left and from behind forwards. (Plate XXXI.) The surface may be distinguished into two parts,—the anterior convex, appearing in the space between the right margin of the sternum and the sinuosity of the left lung; the posterior plane, resting chiefly on the oblique surface of the diaphragmatic tendinous centre. These two surfaces are united by a sharp anterior-inferior margin (*margo acuta*), and an obtuse posterior-superior one (*margo obtusa*). It generally corresponds in size with the fist of the individual; its average weight in the adult is about ten ounces; and its length from the middle of the base to the tip is about five inches. The heart.

The base of the heart is circular, flattened behind, and presents an oblique groove, which indicates the limits between the auricles and the ventricles.

Each auricle is of a tetrahedral shape, and is distinguished into the basilar or membranous part (*sinus venosus*), and the tip or proper auricle (*auricula*), a pyramidal angular process, the structure of which is muscular. The right auricle is the largest, the left smaller.

The ventricles constitute the great part of the cardiac cone. Their anterior and posterior surfaces present each a longitudinal depression (*sulcus longitudinalis superior et inferior*), proceeding from the base to the tip, containing the anterior and posterior coronary vessels, and indicating the situation of the fleshy partition (*septum ventriculorum*) common to both ventricles.

The interior of the right auricle behind presents above the opening of the superior *cava* (*ostium venosum superius*), below that of the inferior *cava* (*ostium venosum inferius*), larger, directed obliquely inward, with an intermediate eminence (*tuberculum Loweri*), denominated after Lower, and the Eustachian valve below (vol. ii. 794). Below and anteriorly is the opening into the ventricle, bounded by a round margin (*ostium inferius*); above is the tip presenting muscular bands (*musculi pectinati*); and within is the partition common to both auricles (*septum auricularum*), with an oval depression (*fossa ovalis*), the residue of the *foramen ovale*, occasionally bounded before by a crescentic slip of membrane.

The right ventricle (*ventriculus dexter vel pulmonalis*) is trilateral pyramidal in shape, with its base above corresponding to the inferior auricular aperture, its apex to that of the heart, the anterior-external wall corresponding with the anterior convex surface of the heart, and the posterior-internal with the common partition (*septum cordis*). It has two apertures—a right superior, communicating with the auricle; and a left superior, communicating with the pulmonary artery.

To the margin of the superior right aperture (*ostium auriculo-ventriculare dextrum*), which is round and thick, are attached several membranous triangular folds (*laciniæ*), with two, or occasionally three *apices*, to which are fixed tendinous chords (*chordæ tendineæ*), with their opposite extremities terminating in muscular cylinders (*musculi papillares, m. teretes*), connected with the fleshy walls of the ventricle. This membranous fold, though often composed of two triangular slips only, is denominated the

three-pointed or tricuspid valve (*valvula triglochin, v. tricuspidalis*). Its *apices* hang into the ventricular cavity, and are prevented by the tendinous chords and their muscular bands from being forced back into the auricle.

The left superior aperture (*ostium arteriæ pulmonalis*), corresponding to the beginning of the pulmonary artery which is attached to it, is placed behind the inner slip of the tricuspid valve, by which also it is covered. The inner margin of the pulmonary artery presents three crescentic or semilunar slips, named the sigmoid valves (*valvulæ sigmoideæ*), with their convex surface towards the ventricle, and the concave one towards the artery, and minute bodies at the middle (*noduli Morgagnii*), corresponding to the axis of the artery.

The interior of the left or posterior auricle presents on the right the two openings of the right pulmonary veins, on the left those of the left pulmonary veins, occasionally uniting in a single aperture, to the right and anteriorly the left surface of the *septum*, bounded before by a small semilunar slip, and below the aperture into the left or aortic ventricle.

The left ventricle has the shape of an obtuse cone, with its base above and behind, and its rounded apex behind and to the left. It is rather larger than the right. The basis has two apertures, a large posterior one, communicating with the auricle (*ostium auriculo-ventriculare sinistrum*); and a smaller anterior, opening into the *aorta* (*ostium aorticum*). To the ventricular margin of the former is attached an irregular membranous slip, not dissimilar to that of the right auriculo-ventricular opening, but always terminating in two apices, to which tendinous chords, connected with tapering muscular bands, are also attached. This has been denominated the bicuspid or mitral valve (*valvula mitralis*). Like the tricuspid, its *apices* hang into the ventricle, and are prevented from being retruded into the auricle by the tendinous chords and papillary muscles.

The aortic aperture, anterior and smaller, corresponds with the commencement of the aorta. Like the pulmonary aperture of the right auricle, it presents three semilunar valves, with the convex surface to the ventricle and the concave to the artery, and with central granules (*corpuscula Arantii*). These valves are occasionally distinguished into anterior, posterior, and inferior or lateral, according to their relation to the plane of the body. In their aortic side are generally small hollows, chiefly occasioned by distension of the aorta, named aortic sinuses.

The heart consists chiefly of muscular fibres, closely united by filamentous tissue, covered externally by the reflected or cardiac portion of the pericardium, and internally by a proper membrane.

Each auricle consists of two parts,—a membranous-muscular, arranged in the stratified mode (*fasciæ*), distinguished as the *sinus;* and a fasciculo-muscular, distinguished as the tip of the auricle, arranged in short parallel bundles (*funes*). The muscular walls of the left ventricle are more than double the thickness of the right; and while those of the latter collapse on division, those of the former retain their original disposition. The fleshy pillars of the interior of the right are small and slender compared with those of the left, which are thick and strong.

The arrangement of the muscular fibres of the heart, which has been studied by Senac, Wolff, Duncan, and Gerdy, is peculiar. Though mutually interlacing, like all the muscles of the entrophic order, the external are arranged in layers (*strata*), while the internal affect the fasciculated form. At the base they are incurvated round the basilar border, and wind obliquely towards the *apex;* but as they approach the latter region, more especially in the *septum*, they observe the longitudinal direction. The assertion of Soemmering, that they are distinguished as being connected without filamentous tissue, is inaccurate.

The adipose tissue at the surface, and towards the base and apex of the heart, appears to be useful in facilitating motion in an organ in incessant action, and forms a soft cushion for the cardiac arteries.

The inner membrane of the heart is thin and transparent. In the right auricle and ventricle, where it is continuous on the one hand with the inner venous membrane, on the other with the inner membrane of the pulmonary artery, it is evidently different from that in the left cavities. It is thinner, and more delicate and transparent. Covering every recess, it is doubled to form the different valvular productions. By Bichat it is believed to be identical with the inner venous membrane; but this is mere supposition. In the left cavities the inner membrane is thicker and more opaque than the right; and its valvular duplicatures, which are much thicker, approach to the fibro-cartilaginous character. This is particularly the case in the aortic sigmoid valves, which often in the healthy adult are firm and elastic, not unlike the palpebral fibro-cartilages. The supposition of Bichat, that it is identical with the inner arterial membrane, with which it is continuous, is, in regard to the ventricle, not improbable.

The heart is supplied with blood from the aorta by means of the right anterior or inferior, and the left superior or posterior coronary or cardiac arteries (*arteriæ cardiacæ*), both issuing from the aortic sinus immediately above the anterior and lateral sigmoid valves. The right or anterior coronary artery, lodged in the superior furrow, after sending several large branches to the *septum* and left ventricle, inosculates at the apex with a large branch of the left or posterior coronary. The latter, which is the largest of the two, after winding round the base of the heart towards the right, is recurvated at the thin margin to the posterior surface, where it runs in the posterior furrow, and is divided into two considerable branches, the larger of which is distributed to the apex; while the smaller, running transversely between the left auricle and ventricle, winds round to the obtuse border, and terminates at the apex, where all the three vessels inosculate freely. The blood is returned by corresponding veins to the coronary, which terminate by one aperture in the right auricle. Its nerves are derived from the pneumogastric and sympathetic.

The four chambers of the heart (*atria, atriola*) are distinguished into pairs,—a right auricle and ventricle communicating mutually and with the pulmonary artery, and a left auricle and ventricle communicating with the aorta. The auricles, separated by the common septum, do not communicate in the natural state; and though in many hearts an oblique opening exists at the anterior margin of the oval depression passing into the left, the crescentic membranous slip by which it is covered prevents the blood of the right auricle from communicating with that of the left. The ventricles are separated also by a thick, fleshy, common partition, through which there is no direct communication, though it was a favourite subject of inquiry before the time of Harvey, to discover communicating apertures.

Capacity of the cardiac chambers.

The capacity of these chambers varies. The right auricle is always more capacious than the left. The two ventricles are, as near as may be, of equal capacity; and the discordant results obtained on this point by numerous inquirers show merely that any variation is accidental or dependent on the state of the organ during the close of life. The blood found in the right ventricle after death varies from $1\frac{1}{2}$ ounce to 3 ounces. The capacity of the left, which is generally empty, is estimated by Meckel to vary from 8 to 20 drachms.

Course of the blood through the cardiac chambers.

The blood contained in the right chambers is modena-coloured or venous; that of the left chambers is scarlet-red or arterial. The former is derived from the *venæ cavæ*, which open into the right auricle; the latter from the pulmonary veins, which open into the left. The direction in which the blood flows on both sides is from the venous apertures into the auricles, thence to the ventricles, and thence to the respective arteries. The venous blood, on reaching the auricle, distends it, and impels its muscles to contraction; and the cavity thus diminished expels the blood in the only direction in which it can proceed,—by the aurico-ventricular aperture into the ventricle. This chamber being distended, its muscular walls all round, especially at the base, contract and diminish its cavity, when the blood, extruded, quits the ventricle in the only direction in which it can, viz. by the aperture of the pulmonary artery. The blood from the pulmonary veins follows the same course in the chambers of the left side. The blood of the ventricles is prevented from returning into the auricles partly by the tricuspid and mitral valves, but chiefly by the annular contraction of the auriculo-ventricular apertures, which are drawn from the margins towards the *septum;* while the latter is shortened, and the *apex* is made to approach the base.

§ 2. THE ARTERIES AND VEINS.

Connected with each ventricle is a large tube, in which the blood flows from the trunk to the branches. The pulmonary artery, the first of these, divaricates into a right and left branch, subdivided and distributed respectively to the right and left lung.

The aorta, which is the second, is the large artery which distributes the blood after aeration in the lungs to the system at large.

The *aorta*, rising from the left ventricle, after giving off the cardiac arteries, makes an antero-posterior incurvation with the convexity upwards, denominated the arch or curvature (*arcus aortæ*). (Plate XXXI. A, A.) From the upper side of this arch arise three large vessels, the *innominata* or subclavio-carotid, the common trunk of the right subclavian and carotid arteries (I), the left carotid (I), and the left subclavian. The aortic trunk, after this curvature, proceeds downward on the left margin of the dorsal vertebræ, giving œsophageal, bronchial, and superior intercostal arteries, thymic, pericardial, and inferior intercostal arteries successively. From the level of this arch to the parabolic opening of the diaphragm at the tenth dorsal vertebra, it is distinguished by the name of *thoracic aorta;* and below this, to the fourth lumbar vertebra, it is the *abdominal aorta*. At its transit through the parabolic aperture it sends off the diaphragmatic arteries.

The vessels issuing from the abdominal aorta may be distinguished into two orders, those which issue from its sides in pairs, and those which issue from its anterior surface singly only. The former consists of the *capsular*, distributed to the renal capsules; the *renal* or emulgent, to the kidneys; the *spermatic*, to the *testes;* and the *lumbar*, to the lumbar muscles, and that region generally. The latter are three in number only, the *cœliac*, *superior mesenteric*, and *inferior mesenteric*. Opposite the fifth lumbar *vertebra*, or the fibro-cartilage uniting the fourth and fifth, the aorta terminates by divaricating into two large lateral trunks, the common or primary iliacs (*iliacæ communes*); while from its middle behind proceeds a small *azygos* artery, distinguished as the *sacro-median*, along the median line of the *sacrum*. In this course the aorta is placed in the posterior angle of the thoracic and abdominal serous membranes, and, inclosed by the anterior vertebral filamentous tissue, sends from its posterior surface numerous arteries to the vertebral column and spinal chord.

The distribution of the branches of the aorta may be understood from the following tabular view.

- Common carotid.
  - External carotid.
    - Superior thyroid.
    - Pharyngeal.
    - Lingual.
    - External maxillary.
    - Occipital.
    - Post-auricular.
    - Temporal.
    - Internal maxillary.
  - Internal carotid.
    - Ophthalmic.
    - Posterior communicating.
    - Anterior cerebral.
    - Middle cerebral.
- Subclavian artery.
  - Subclavian portion.
    - Vertebral.
    - Inferior thyroid.
    - Suprascapular.
    - Transverse cervical.
    - Ascending cervical.
    - Deep cervical.
    - Internal mammary.
    - Superior intercostal.
  - Axillar portion.
    - External thoracic.
    - Infrascapular.
    - Circumflex humeral.
  - Brachial portion.
    - Deep humeral.
    - Anastomotics, or Articulars.
    - Radial.
      - Radial recurrent.
      - Superficial volar.
      - Dorso-radial of the thumb.
      - Dorso-radial of the fore finger.
      - Annular—deep arch.
    - Ulnar.
      - Ulnar recurrents.
      - Interosseal.
      - Nutritious.
      - Volar or palmar—superficial arch.
- Common iliac.
  - Posterior iliac or hypogastric.
    - Ileo-lumbar.
    - Sacral-lateral.
    - Obturator.
    - Gluteal.
    - Ischiatic.
    - Internal pudic.
    - Umbilical.
    - Vesical.
    - Middle hemorrhoidal.
    - Uterine.
    - Vaginal.
  - Anterior or external iliac.
    - Inguinal portion.
      - Epigastric.
      - Circumflex iliac.
    - Deep femoral.
      - Circumflex femoral.
      - Perforating.
    - Superficial femoral popliteal.
      - Superior articular.
      - Inferior articular.
      - Internal inferior circumflex.
      - External inferior circumflex.
      - Anterior tibial.
        - Dorsal of the foot. } Deep plantar arch.
      - Posterior tibial.
        - Internal plantar. } Deep plantar arch.
        - External plantar—superficial arch.
      - Peroneal.

Special Anatomy.

In general the denominations of these arteries indicate the parts to which they are distributed. In the ultimate distribution of the arterial system, however, there is great variety; and it is often impossible to determine the exact origin, course, and distribution of the smaller terminations. The trunks alone are constant in position. In distribution, the following general rules are observed:—1*st*, The arterial trunks send small lateral branches to the parts between which they run 2*dly*, The majority of individual organs are supplied, not by one proper vessel, but either by one principal artery and two or more subordinate ones, or by several subordinate ones. 3*dly*, A trunk, after giving off several lateral branches, may either terminate in one vessel, which is ultimately distributed to the organs to which it is destined; or it may divaricate into several, none of which may be considerable enough in size, or direct enough in course, to be regarded as the proper terminal vessel. Thus it is often difficult to determine whether the temporal artery or the internal maxillary is the continuation of the external carotid, which of the palmo-digital arteries is the continuation of the radial, whether the anterior or the posterior tibial artery is the continuation of the popliteal, and whether the dorsal of the foot is the termination of the former. 4*thly*, In the terminal vessels, where inosculation is frequent, it is impossible to determine whether an artery arises from one trunk or another. Thus in the arterial arches of the hand and foot, in which the digital vessels issue from the convexity of the arch, it is impossible to say whether these arteries arise from the radial or the ulnar in the one case, or the anterior or the posterior tibial in the other.

The arteries are accompanied by veins, which in general correspond, for the purpose of conveying the residual blood, after distribution, to the right chambers of the heart, to be transmitted by the pulmonary artery to the lungs for renovation. The veins of the head, chest, and superior extremities, open into the *superior cava;* those of the lower part of the trunk, the pelvis and pelvic extremities, terminate in the *inferior cava;* the veins of the stomach, intestinal canal, spleen, and pancreas, terminate in the portal vein; and the regredient hepatic veins are united in one vessel, which terminates in the upper end of the *inferior cava.*

SECT. II.—THE ORGANS OF AERATING CIRCULATION, OR RESPIRATION.

The lungs are two soft, spongy, vascular bodies, contained in the cavity of the chest, one on each side, and imitating in shape the internal figure of that region. Each lung, resembling somewhat a cone, with one side truncated, and the base obliquely cut, is distinguished into a convex external surface, corresponding to the concave internal one of the *thorax;* a flat inner or mesial surface, corresponding to the *mediastinum;* a rounded obtuse *apex*, corresponding to that of the *demithorax;* and a concave base directed obliquely from the mesial plane to the hypochondres, corresponding to the convex surface of the diaphragm.

Each lung is distinguished into lobes (*lobi*) separated by fissures (*incisuræ*). The right, which is the largest, consists in general of three lobes, the *superior*, *middle*, and *lower;* the left of two only, an *upper* and *lower*. The mesial margin of the left is distinguished from that of the right by a sinuous notch, indicating the situation of the heart (*fovea cardiaca*).

The intimate structure of these bodies, which has been the subject of much research, depends on the nature of the tubes which are distributed to them, and of which chiefly they consist. These are the bronchial or breath-tubes (*bronchi*), the continuations of the windpipe, and the branches of the pulmonary artery and veins.

Special Anatomy.

The windpipe (*trachea*) is a cylindrical tube, about four or five inches long, extending from the cricoid cartilage, to which it is attached by a fibro-mucous membrane behind the sternum, to the level of the third dorsal *vertebra*, or the fibro-cartilage between it and the second. (Plate XXXI. T.) It consists of from 17 to 18 or 20 cartilaginous rings (*annuli*), truncated behind, united by a fibrous membrane without, continuous, but particularly firm in the interannular spaces, and along the whole posterior part of the canal. These fibres are white, firm, longitudinal, and closely set. Within is the mucous membrane, continued from the larynx to the *bronchi*, resting on filamentous tissue, in which are embedded the mucous follicles. By many, muscular fibres have been represented to exist between the rings; according to Soemmering transversely and longitudinally; and Reisseissen has recently maintained their reality at the posterior part of the tube. Their fibrous disposition is undeniable, but their muscular character may be doubted.

The windpipe, covered before by the thyroid gland, and corresponding to the sigmoid pit of the sternum, is attached to the œsophagus behind by filamentous tissue.

Opposite the third dorsal vertebra the *trachea* is bifurcated into two tubes named air-tubes (*bronchi*), which are directed obliquely to each lung with a mutual intermediate angle of about 35°. The right is about one fourth larger and one fifth longer than the left. Both are cylindrical, but divaricate at their lower end, where they sink into the substance of the lungs, into several smaller tubes (*bronchia*), which again ramify and subdivide into tubes still smaller, and successively. The interbronchial angle is occupied by lymphatic glands, which are also arranged round the tubes.

The *bronchi* consist of cartilaginous rings, complete above, but parted into three annular segments between the middle and lower ends, united by whitish fibrous tissue, longitudinal externally, transverse within, and lined by mucous folliculated membrane. As they advance into the substance of the lungs, and are still more minutely divided, the cartilages diminish in size and firmness, and their place is supplied by fibrous tissue of transverse circular fibres, which at length also disappear, and mucous membrane alone is left.

These transverse annular fibres have been supposed by Haller, Soemmering, and recently Reisseissen, to be muscular. It is not improbable that they are so; but no positive proof of this fact has yet been adduced, and they appear rather to belong to the elastic fibrous system.

The larger bronchial tubes are accompanied each by an artery derived from the aorta or the subclavian, and following their ramifications into the pulmonic substance. The blood conveyed by these vessels is returned either to the *vena azygos* or the superior *cava.*

The pulmonic or final divisions of the bronchial tubes terminate in blind sacs covered by mucous membrane, and communicate with each other, forming an appearance of intersecting compartments, which have been distinguished by the name of *air-cells* (*cellulæ aereæ*), or pulmonic vesicles (*vesiculæ pulmonis*). They are represented as polygonal and irregular, and about one eighth or one tenth part of a line in diameter. (Haller and Soemmering.) On the whole, these air-cells appear to be merely the terminations of the bronchial tubes mutually communicating, lined by a very delicate mucous membrane.

The pulmonary artery, ramified and subdivided to a great degree of minuteness, communicates most freely with a number of vessels, which may be traced into trunks terminating in the pulmonary veins. This capillary system, enveloped in filamentous tissue, is distributed beneath the mucous membrane of the terminal bronchial tubes or communicating cells. The exterior surface of this filamentous tissue is covered by the *pleura.* From

Special Anatomy.

these facts it results that the lung consists of cartilaginous and fibrous tubes mutually intersecting, and the capillary communications of the pulmonary artery and veins, inveloped in filamentous tissue, lined on one side by mucous membrane, covered on the other by transparent serous membranes. The air-cells, lined by mucous membrane, have no communication with those of the filamentous tissue, as some have absurdly imagined. Except this filamentous tissue, the lung has no proper substance or *parenchyma;* and its structure is entirely filamento-vascular.

In the capillary vessels of the pulmonary artery and veins, the venous or modena blood, exposed to the influence of the inspired air through the thin bronchial membrane, parts with its dark, and gradually acquires a bright red tint. This may be styled the aerating or arterializing capillary system.

The lung, however, receives other vessels, the bronchials, by which its mucous aerating membrane and submucous tissue are nourished. Entering with the bronchial tubes between the folds of their *pleura*, these vessels are subdivided as they proceed, and at length form a minute network on the attached surface of the bronchial mucous membrane.

The lung derives its nerves from the eighth pair chiefly, and a few filaments from the great sympathetic. The lung is well supplied with lymphatics, both superficial and deep.

SECT. III.—THE ORGANS OF SECRETORY CIRCULATION, OR SECRETION.

Of the organs of secretory circulation, several, as the lacrymal gland, the salivary glands, the liver, and pancreas, have been already considered; and others, for example the *testes*, will fall under subsequent heads. This, however, is the proper place to notice the organs of the urinary secretion, which consist of two glands, the kidneys, and two excretory ducts, the ureters, terminating in a common receptacle, the bladder.

The kidneys.

The kidneys (*renes*) are two glandular bodies situate in the posterior or lumbar part of the abdominal region, one on each side of the lumbar vertebræ, behind the peritoneum, and before the *psoas* muscle and part of the diaphragm, with the *quadratus lumborum* behind and laterally, and enveloped in a thick layer of adipose tissue.

The right kidney is below the liver, above the cæcum, behind part of the duodenum, colon, and the right extremity of the pancreas. The left is bounded above by the spleen, by the transverse arch of the colon before, and it has the sigmoid flexure below. The right kidney is about two inches from the outer margin of the *vena cava*, and the left at about the same distance from the outer margin of the aorta.

The situation of the right kidney is generally lower than that of the left, so that part of its lower extremity is in the iliac *fossa*, while the lower extremity of the left is quite above the margin of the ilium.

Resembling in general shape the large French bean, named from it, each kidney may be described as an oblong body, convex externally and at both ends, and with a sinuosity at its inner margin, named the renal fissure (*fovea renis*), in which the vessels and excretory duct are contained. Each kidney is between four and five inches long, and two broad; and the weight of each varies from three to four ounces. The anterior surface, corresponding but not attached to the outer surface of the peritoneum, it convex, but becomes hollow at the inner margin, where it terminates in the renal fissure. The posterior surface, which is less convex, is separated from the internal aponeurosis of the transverse abdominal muscle, the diaphragm, and the *psoas magnus*, by a thick layer of adipose tissue.

The kidney consists of glandular structure, invested by a firm membrane, somewhat fibrous in appearance.

Structure.

In the glandular structure the anatomist recognises the most distinct example of this form of tissue. It consists of two parts, a granular external, and a tubular internal. The former, which occupies the exterior of the kidney, is a homogeneous substance, of a yellow fawn colour, and consists of minute spherical or spheroidal granules (*granula*), aggregated together by filamentous tissue, and forming at their exterior calycoid or cup-like cavities, in which the round *fundi* of the tubular conoids are lodged. In these the capillary vessels of the kidney are ramified with great minuteness. The tubular part consists of very minute capillary tubes (*tubuli uriniferi, tubuli Belliniani*), varying in length, united by filamentous tissue, and arranged in parallel juxtaposition, so as to form conoids with globular bases, which are lodged in the cup-like cavities of the granular portion, and rounded *apices* directed to the renal fissure. The number of these tubular cones varies from 10 or 12 to 18 or 20. Their apices form an equal number of nipple-like processes (*papillæ*), covered by a thin membrane almost transparent, in which are numerous minute holes, apertures of the tubes of which the cones are composed. These apertures, however, are much less numerous than the tubes, several of which are united in one common orifice. The renal *papillæ* thus constituted project into a series of conical cavities, formed within of the papillary membrane, without of fibrous *strata* and filamentous tissue. These cavities, which from their shape are denominated funnels (*infundibula, calyces*), uniting into three or four larger ones, terminate in a considerable membranous sac named the basin (*pelvis*) of the kidney.

These two parts of the kidney are distinguished not only in structure but in colour and consistence. While the granular part is fawn-coloured, and somewhat soft and flabby, the tubular is pink-red, fleshy and firm; and the boundary line is distinct. The tubular cones are separated from each other by partitions, which appear to be filamentous tissue.

There is no doubt that the granular is the secreting part of the gland; and the tubes are merely conduits of the urine, which indeed may be expressed from their apertures. It is important, however, to determine the mode in which the two portions communicate. The assertion of Ferrein and Eysenhardt, that the tubes are blind canals, is inaccurate in this respect, that the terminal tubes evidently communicate with others in the interior of the cones, which again are immediately connected with the granular part. It further appears, that in the granular part there are very minute white tortuous canals, which appear to communicate with the straight tubes of the cones. All beyond this is entirely conjectural.

The kidney, therefore, cannot be said to possess *parenchyma* or proper substance. The idle distinctions into cortical and medullary ought to be rejected as remnants of an exploded theory.

Blood-vessels.

The kidneys are supplied with blood from the aorta by the renal arteries. Issuing at right angles from the lateral regions of the abdominal aorta, below the superior mesenterics, these vessels pass directly into the fissure at its superior and anterior part, the left behind, the right occasionally before the renal vein, but crossing its direction. The calibre of these vessels is considerable, about three lines at least; and they have been estimated to convey the sixth part of the blood of the abdominal aorta. The left artery is about one inch long, the right is the whole breadth of the vertebral column longer. In the renal fissure each artery divaricates into three or four consider-

Special Anatomy.

able branches, which enter the kidney a little above the attachment of the basin (*pelvis*). These vessels are again subdivided into an anterior series before, and a posterior cluster behind the *infundibula*, which they accompany to the *papillæ*. Dividing more minutely, they form anastomotic arches, from the convexity of which proceed minute vessels, radiating into the granular substance of the gland. These vessels are distributed principally to the granular matter at its calycoid surfaces, in which the tubular cones are lodged.

The veins are arranged exactly in the same manner, and connected with the renal trunk, much as the arterial branches are connected with it.

The kidney is supplied with nerves, accompanying the arteries, derived from a plexus inclosing the renal trunk, and which is originally formed from filaments of the solar of the great sympathetic.

The basin or *pelvis*. The pelvis consists externally of a prolongation of the renal investment, a proper middle membrane, white, opaque, and fibrous, and an inner lining, which, though thin and semitransparent, presents the character of mucous membrane.

The upper extremity of each kidney is covered by the renal capsule, a substance of no peculiar structure, and the nature of which is unknown.

The ureters. The basin forms the common termination of the renal funnels, and the commencement of the ureter. This is a membranous tube, of the diameter of a moderate-sized quill, passing between the renal basin, behind the peritoneum, to the posterior and inferior part of the bladder, in which the lower extremity opens. Each ureter is inclined to the mesial plane below. The right ureter is on the outside, and nearly parallel with the inferior cavity. Both cross the *psoas* at an acute angle, and below the common iliac arteries and veins. In the pelvis they cross the *vas deferens* in the male, and on reaching the bladder pass obliquely, from eight lines to an inch, through its coats, and open in the posterior margin of the lower *fundus* of that organ.

These tubes consist of fibrous membrane, lined by mucous and covered by filamentous tissue. It contains no muscular fibres, notwithstanding the assertions of some.

The ureters are supplied with blood derived from the renals, occasionally from the lumbars and spermatics, but more especially from the aorta by two ureteric arteries.

The urinary bladder. The urinary bladder is a muscular membranous bag, spherical above and cubo-spherical below, placed on the lower region of the pelvis, behind the pubal symphysis, and before the *rectum* in the male, and the *uterus* in the female. From the peculiarity of its figure and relations, it is distinguished into a superior *fundus*, spheroidal, directed to the abdominal cavity; an inferior *fundus*, cubo-spheroidal, between the ureters and urethral opening; a neck (*cervix*), pyriform at the latter point; an anterior surface, corresponding to the posterior of the pubal symphysis; a posterior, corresponding to the rectum in the male and the uterus in the female; and lateral regions, corresponding to the ilio-ischial inner surface, and those of the *obturator internus* and *levator ani*.

In females generally the transverse extent of the bladder is greater than in the male, and in females after child-bearing than in the virgin. In infancy its superior fundus is pointed and conical rather than globular,—a peculiarity derived from its fœtal shape, which is pointed, with the *urachus*, a ligamentous chord proceeding to the navel, attached.

Structure. The bladder consists of a muscular coat, covered above, behind, and laterally by peritoneum, and lined by mucous membrane.

The peritoneal covering is continued from the anterior surface of the rectum, and the lateral regions of the pelvis over the posterior and lateral and part of the superior surfaces of the bladder, all of which are free; while the inferior *fundus*, the neck, and the anterior, are covered by filamentous tissue, connecting the organ to the neighbouring parts. This filamentous tissue is abundant, especially below.

Special Anatomy.

The muscular coat, always distinct, varies in thickness in different individuals. In females, so far as we have observed, it is rather thicker than in males. The fibres run in all directions, but are strong at the superior surface, where some anatomists have arbitrarily distinguished them by the name of *detrusor urinæ*. There are no fleshy pillars, mentioned by some, in the healthy state.

The neck is surrounded by a thick range of circular fibres, which has been denominated the *sphincter* of the bladder.

The mucous membrane, without *villi* or *epidermis*, is extended over the whole inner surface of the organ, and is continuous behind with that of the ureters, and before with that of the urethra. The space inclosed between these three orifices is named the vesical triangle (*trigonus vesicæ*); and a minute duplicature of the mucous membrane at the urethral orifice is denominated the *vesicæ uvula*.

The bladder is supplied with blood chiefly from the posterior iliac or hypogastric trunk, by means of the common pudic, the obturator, the ischiatic, and the hemorrhoidal. Of these, one vesical artery proceeds from the hemorrhoidal; another often comes off directly from the hypogastric as an inferior vesical; and in some instances they issue from the umbilical. The vesical nerves are partly from the sympathetic, partly from the sacral.

The capacity of the bladder varies in different individuals. In the female it is generally more capacious than in the male. In the healthy state it may contain a pound of urine, without extreme distension; and it is often capable of containing two, three, or four pounds. Its situation varies at different periods of life, and in different degrees of distension. In the fœtus and infant, when the pelvis is small, the bladder is contained in the abdomen. In the adult in the ordinary state it is within the limits of the pelvis; but when much distended, its superior *fundus*, rising above the *pubis*, is in the abdomen. During pregnancy, also, it is thrust forwards and upwards by the gravid womb.

Urine, the fluid secreted by the kidneys, is particularly distinguished by containing, with various saline substances, *urea*, an animal principle containing 46 per cent. of azote. As the saline ingredients also abound in principles containing this element, it may be inferred that the chief purpose of the kidneys is to remove from the system a considerable proportion of nitrogen, which would either be injurious by its presence, or disturb the due proportion of the other elements.

The urethra, which terminates the urinary apparatus, is nevertheless common to it with the reproductive organs. The male urethra especially is more connected with the reproductive than the secretory organs. In the female, in whom alone this canal is proper to the latter, it is a short muco-membranous tube, terminating in a papillated orifice in the superior anterior wall of the vagina.

PART III.

ANATOMY OF THE ORGANS PERTAINING TO THE REPRODUCTIVE FUNCTIONS.

These organs, by the possession of which the individuals of the human race are distinguished into two sexes, male and female, consist in the former of impregnating, and in the latter of the impregnable organs. The former may be again distinguished into preparing and transmitting

Special Anatomy

organs; and the latter into receiving and ootrophic organs, or those which nourish the product of generation.

CHAP. I.—THE MALE OR IMPREGNATING ORGANS.

The male organs consist of two glandular organs, named testicles with excretory ducts, for secreting the impregnating fluid, and an organ for transmitting it to those of the female.

The testicles (*testes*) are two ovoidal bodies contained on each side of the mesial plane in a cutaneo-cellular sac named the *scrotum*, attached to the anterior inferior part of the pubal *symphysis*.

The scrotum.

The *scrotum* consists of skin with very thin corion, resting on loose filamentous tissue, which forms on the mesial plane a thick wall, separating the right half of the scrotal bag from the left. On the median line is a superficial groove, named suture (*raphe*), at which the corion and filamentous tissue, elsewhere loose, are united into a solid and firm substance. Most of the old anatomists mention a muscular layer known by the name of *dartos*, and to which they ascribe the contraction of the scrotum on exposure to cold; but the existence of this muscular layer is not supported by inspection. The scrotal skin is well supplied with arteries, and especially veins connected with those of the epigastric, external iliac, femoral, obturator, and external pudic, the branches of which anastomose freely. The nerves are from the lumbar, obturator, and crural.

The scrotal filamentous tissue incloses on each side a thin membranous sac of a pyriform shape, with the base below, and tapering to a neck above. Adherent on the outside to the filamentous substance, this membranous sac is free and smooth within, except at the neck, where it embraces a part distinguished by the name of spermatic chord. This, which is the sheath-like or vaginal coat (*tunica vaginalis*), is distinguished into two parts, an inferior pyriform, forming a cavity for the testicle, and a superior cylindrical, covering the spermatic chord, and adhering to it. This membrane is said to be fibrous externally; but it appears to be merely condensed filamentous tissue. Within it is evidently a transparent serous membrane, both in qualities and distribution. It is continued from the adherent part of the chord downward, and over the testicle.

The vaginal coat.

The albugineous coat.

Within the cavity of the former are contained the testicles, both suspended by the spermatic chord, with the *epididymis* behind. Their substance is inclosed in a firm, opaque, white, fibrous investment, covered by a thin transparent membrane, reflected from the vaginal coat. The former is the *tunica albuginea*, or proper tissue of the gland; the latter is the vaginal coat of the testicle (*tunica vaginalis testis*).

The testicle.

The testicle consists of minute irregular-shaped granules, of a white or gray-white colour, soft, closely compacted, and with numerous capillaries distributed through them. More minutely examined, these are found to be capillary tubes of extraordinary length, folded on themselves, and contorted so as to occupy a small space, and when unfolded extending, according to some anatomists, 16 feet, according to others to 25 or even 100 ells. These long tortuous tubes, which are named the seminiferous (*ductus seminiferi*), are estimated at about 300 in number. They communicate by one extremity with the blood-vessels and lymphatics of the testicle, and by the other, after several unite into one common duct, terminate in about 20 larger tubes, denominated egredient ducts (*vasa efferentia*), which, united in a cluster by means of filamentous tissue, and invested by part of the *tunica albuginea* form at the upper part of the gland a whitish cylindrical body, about six lines long and two broad, distinguished by the name of the process of Highmore (*corpus Highmori*). These efferent vessels unite and form a single tube of great length, which, folded on itself by innumerable turns, connected by filamentous tissue, and invested by *tunica albuginea*, constitutes the *epididymis*, attached by its *head* to the testicle, and by an incurvated extremity named *tail*, continuous with the common excretory duct (*vas deferens*).

The seminiferous tubes.

The process of Highmore.

The epididymis.

The vas deferens or seminal excretory duct.

The latter is a long fibro-cartilaginous tube, ascending upwards from the tail of the epididymis, and making part of the spermatic chord, with which it enters the abdomen at the inguinal aperture. At the inner margin of this it separates from the chord, and descends into the pelvis, first by the side, then at the posterior and inferior *fundus* of the bladder; and, approaching that of the opposite side with the *vesicula seminalis* on the outer margin, each *vas deferens* is in contact with the other at the base of the prostate gland. Here each receiving a tube from the corresponding *vesicula*, forms a common duct (*ductus ejaculans*), which traverses the prostate, and terminates in the urethra about one inch and a half from its vesical end, on each side of the eminence named *verumontanum*.

Spermatic chord.

The spermatic chord, by which the testicle is suspended, consists of the spermatic artery or its divisions, derived in general from the *aorta*, two or three spermatic veins, several lymphatics, and the *vas deferens*, inclosed in filamentous tissue, and covered by a slip of muscular fibres denominated the suspensory muscle (*cremaster*, *tunica erythroides*), detached partly from the internal oblique and transverse of the belly, fixed partly at the inner surface of the ligament of Poupart and the tuberosity of the pubis.

The spermatic artery divaricates into several branches, which are distributed, after a few sent to the *epididymis*, among the seminiferous ducts. They communicate with numerous tortuous veins, which are collected into a cluster known by the name of the *pampiniform body*, situate immediately below the *tunica albuginea*.

Seminal vesicles.

Below the inferior *fundus* of the bladder, on the outside of that organ, are placed two bodies, oblong, flattened, pyriform, with the base behind, composed at first sight of a series of cells separated by *septa*. Each of these bodies, which have been named the seminal vesicles (*vesiculæ seminales*), consists of a long tortuous membranous tube, convoluted on itself, and with the folds aggregated by bridles of filamentous tissue, which convert it into communicating sacs. The cavity of this canal, which communicates with the urethra by a tube, common to the vesicles and the *vasa deferentia*, has been supposed to serve as a reservoir for the seminal fluid after secretion by the testicles; but this supposition is by no means verified, and is open to several objections.

The transmitting organs consist of the *penis* with the urethra and prostate gland.

The cavernous body.

The *penis*, the shape of which is well known, consists, of two parts, the cavernous body (*corpus cavernosum*), and the spongy body (*corpus spongiosum*) containing the urethra. The cavernous body, single before, bifurcated behind, may be described as two cylindrical bodies, inclosed in a fibrous investment, which, uniting them on the mesial plane, forms a partition (*septum medium*), perforated nevertheless with orifices for vessels. The divaricating posterior extremities (*crura*) are firmly attached to the ischio-pubal *rami* on each side. The intermediate triangular interval is occupied by the perineal filamentous tissue, fat, the perineal muscles, and the spongy body in the middle. Above and before, both are connected to the pubal symphysis by a triangular, flat, fibrous substance, named the *triangular* or *suspensory ligament*.

The spongy body.

The spongy body is a cylindrical cellulo-vascular tube, inclosing the urethra, and occupying the middle depression, along the lower surface of the cavernous body, from its anterior extremity, where it constitutes the *glans*, to the angular bifurcation of the cavernous body, where it is expanded into a substance denominated the *bulb* of the urethra. The spongy body is invested on the side and below by integuments only.

Their structure.

Both these parts, but especially the cavernous body, consist of numerous minute arteries, communicating directly with elongated and dilatable veins, and constitute the best example of erectile arrangement in the body. The injection of these vessels constitutes the erection of the penis, and induces the contraction of the urethra necessary to expel the seminal fluid. The two extremities of the spongy body, the *glans* before and the bulb behind, form the limits of the erectile tissue round the urethra. The anterior extremity is covered by loose skin, which forms the foreskin (*præputium*), and, in the shape of a thin semi-mucous corion, provided with epidermis, is continued over the glans, from which it passes insensibly into the mucous membrane of the urethra.

With the penis several muscular organs are connected The *ischio-cavernosus* and *transversus perinæi* on each side connect the cavernous body to the *ischium;* and the *bulbo-cavernosus* connects it to the bulb of the *urethra.* Mr Houston of Dublin has lately discovered a packet of muscular fibres situate between the pubal arch and the penis on each side, which, by compressing the dorsal vein, may, he imagines, contribute to erect the organ.

The cavernous and spongy bodies are supplied with blood from the terminal end of the internal pudic artery, by means of two vessels, the *cavernous* and the *dorsal.* The bulb receives branches from the transverse perineal artery.

The prostate gland.

The prostate gland is a body cordiform or flat conoidal in shape, with the base behind and the apex before, corresponding to the vesical end of the urethra, situate behind the pubal symphysis before, and below the neck of the bladder, in the angle between it and the *rectum*, and between the *levator ani* of each side.

It is distinguished into three lobes,—two lateral, united on the mesial plane,—and a small cellulo-vascular slip in the angle between them, towards the base. In structure it is composed chiefly of minute arteries and veins ramified in a firm, fleshy, filamentous tissue, amidst which are placed follicles with minute ducts, which terminate in larger tubes, varying in number from seven to twelve, the apertures of which are on the sides and the surface of the urethra. These follicles secrete a viscid liquor, the use of which is unknown. From the fact, however, that, when the prostate gland is diseased or injured, the sexual appetite is languid or extinguished, it may be inferred that the prostate is essential to the generative functions in the male. It is analogous to the *uterus* in the female.

Cowper's glands.

With the prostate may be mentioned the accessory glands of Cowper, two small bodies, oblong-round, placed on each side of the urethra, before the prostate. They appear to be mucous follicles on the large scale.

The urethra.

The urethra is a membranous canal, extending from the neck of the bladder in the pelvis to the extremity of the glans, where it terminates on the surface by an aperture (*orificium urethræ*), consisting of two lateral segments. Its length and width vary in the erect and unerected state of the penis. In the latter it is about seven or eight inches long, and its calibre is about three lines, but admitting of distension beyond this. According to the parts with which it is connected, it is distinguished into four different portions; 1*st*, the *prostatic*, about one inch; 2*d*, the *membranous*, from one to one inch and a half; 3*d*, the *bulbous*, scarcely one inch; and, 4*th*, the *spongy* portion, occupying the anterior part of the canal, inclosed by the spongy body.

The surface of the urethra is a mucous membrane supplied with follicles, and moulded into blind sacs named *lacunæ*, which appear to contain mucous ducts. Its capacity varies in different parts. Wide at the middle of the prostate, it is contracted in the membranous part, which is indeed the narrowest of the canal; it enlarges again in the bulb; and from this it preserves the same diameter to immediately behind the *glans*, where it forms a dilatation distinguished by the name of the navicular (*fossa navicularis*). The apertures in this canal have been already mentioned to be, besides that of the bladder, one ejaculatory on each side of the *veru-montanum*, from seven to ten excretory apertures from the prostatic ducts, and one aperture from each accessory gland. The mucous membrane of the membranous and spongy portions presents longitudinal folds, which appear to be connected with the occasional distensions of the tube for the expulsion of the urine.

The urethra, straight in direction on the mesial plane, is incurvated within the pelvis from behind forwards, so that its concave incurvation incloses the pubal arch, while its convexity is turned to the perinæum. The pendulous state of the *penis*, when unerected, causes it to acquire another incurvation without the pelvis, with the convexity directed upward. These curvatures are considerably exaggerated in engravings. The first round the arch of the pubis is much less angular than it is delineated.

CHAP. II.—THE FEMALE OR OOTROPHIC ORGANS.

The female generative organs consist of the ovaries, the uterine or Fallopian tubes, the womb, and the vagina. These organs are contained in the pelvis.

The ovaries.

From the time of Steno, anatomists have given the name of ovaries or eggbeds (*ovaria*) to two ovoidal bodies, about the size of a pigeon's egg, placed one on each side of the womb in the pelvis, in a duplicature of peritoneum termed the broad ligament (*ligamentum latum*) of the *uterus*. Convex and free on their anterior and posterior surfaces, and tapering towards each extremity, their lower margin is straight or slightly concave, with a vascular sinuosity. The external extremity is contiguous to a round solid chord (*ligamentum teres*), forming the anterior margin of the broad ligament, and proceeding from the womb to the internal orifice of the inguinal canal and the pubal extremity of the ligament of Poupart, and by which the uterus is retained in the pelvis. Each ovary weighs about one drachm and a half.

Ovarian vesicles or germs.

Covered externally by peritoneum, stretched over a fibrous membrane of some firmness, the ovaries consist of a pulpy brownish-gray substance, very vascular, in which are embedded minute bodies of vesicular appearance and oval shape, varying in number from 15 to 20. These bodies, which, from the time of De Graaf at least, have been regarded as ova or embryal atoms or germs (*ova Graafiana, ovarii vesiculæ*), consist of a thin membrane containing a viscid, reddish, or yellow fluid.

The ovary is supplied with blood from arteries analogous to the spermatic of the male.

Previous to puberty the ovaries are smooth in surface and entire. After this period, both in females who have had children, and even in virgins, they are marked on the surface by minute depressions, which have been denominated *cicatrices*, and which are believed to be the consequence of minute breaches of the ovarian tunics, occasioned by the escape of the vesicles from the surface of the ovary. There is no proof that these cicatrices are the invariable result of sexual intercourse. Small before puberty, at that period they acquire considerable size, and

Special Anatomy.

retain them till the age of 45 or 48, after which they shrivel and shrink to a very small size.

Uterine tubes.

The Fallopian or uterine tubes are the excretory ducts of the ovaries. They are cylindrical tubes about four or five inches long, contained in the anterior fold of the superior margin of the broad ligament, between the round ligament and the ovary, and connected by their lower extremity with the superior angles of the womb. Their superior extremity, which is loose, is surrounded by a fringed or laciniated slip of peritoneum, in the centre of which is seen the upper or peritoneal aperture (*orificium superius*), larger than the calibre of the canal, which admits a hog's bristle, but contracts at the lower or uterine extremity (*orificium uterinum*), which is situate in the upper angle of the inner surface of the womb.

Covered by serous membrane externally, lined by thin mucous membrane with follicular glands, the Fallopian tubes consist of fibrous tissue interposed between these two. Below, however, at their junction with the womb, they seem to partake of the structure of that body.

The womb.

The womb (*uterus, matrix*) is a hollow organ with thick walls, shaped like a conoid, flattened before and behind, situate on the mesial plane in the pelvic cavity, between the bladder before and the rectum behind. Small before puberty, at that period it is about $2\frac{1}{2}$ inches long, $1\frac{1}{2}$ broad at its widest part, and weighs from 7 drachms to $1\frac{1}{2}$ ounce. It is distinguished into the *fundus*, body (*corpus*), and neck (*cervix*); the first free, directed upwards; the second also free, between the bladder and rectum; and the third connected within and below to the *vagina*. At each side of the *fundus* is a corner or angular part, which communicates with the uterine extremity of the Fallopian tube. The neck of the womb may be distinguished into the external or peritoneal, and the internal or mucous neck, which terminates in an elliptical opening, with rounded, thick, firm margins, not unlike the mouth of the tench, and named therefore *os tincæ*, as well as *os uteri*. These lips become rough and irregular in women after child-bearing, in consequence of the distension during parturition.

The cavity of the womb is small compared with the volume of the organ, in consequence of the thickness of its containing walls. It is triangular in shape, with the base at the *fundus*, and the apex at the neck. The superior angles are small recesses, in which the uterine extremity of the Fallopian tube of each side opens. The cavity is much contracted at the neck, forming a short cylindrical canal, the lower aperture of which is the *os uteri*, communicating with the *vagina*.

Structure.

Covered externally by peritoneum, the womb consists of a peculiar thick, firm, whitish substance, lined by mucous membrane. This intermediate matter, though neither red nor distinctly fibrous, has been very generally regarded as muscular. Its contractile powers during parturition it is impossible to doubt. But while it is difficult to reconcile this phenomenon with the absence of muscular tissue, it must be allowed that it is much more easy to maintain than demonstrate the unequivocal appearance of muscular fibres. On this topic the reader may consult a paper by Mr Charles Bell, in the 4th volume of the *Medico-Chirurgical Transactions;* and an elaborate account of the different ranges of muscular fibres in the uterus, by Madame Boivin, an eminent Parisian *accoucheuse*, in her *Mémorial de l'Art des Accouchemens*, Paris, 1824.

The uterine mucous membrane is thin, but reddish-gray, villous, and marked by numerous pores, the apertures of blood-vessels, most probably those which secrete the menstrual fluid. At the neck it is provided with muciparous glands, which are the seat of several of the forms of leucorrhœa.

The blood-vessels of the uterus are derived partly from the spermatic, partly from the hypogastric. The former, after passing between the folds of the broad ligaments, and giving branches to the tubes, enter the uterine substance by its lateral regions. The second, named the *uterine*, after sending branches to the vagina and neighbouring parts, ascend along the margins of the organ, and are distributed to its *fundus*.

The uterine veins correspond to the arteries in course and connections. In the walls of the organ they form large sinuses, very distinct after parturition.

The uterine lymphatics are connected with those of the pelvis and hypogastric region. The nerves, which are numerous, proceed from the lower extremity of the great sympathetic, from the renal plexus, the spermatics, the last lumbar nerves, and the sacral.

The womb is the proper ootrophic organ, to the inner surface of which the *ovum* is attached by a vascular body denominated the *placenta* or after-birth.

The vagina.

The *vagina* is a membranous vascular tube, situate on the mesial plane, behind the pubal arch and *urethra*, and before the *rectum*, and extending from the neck of the womb in the pelvic cavity to the external outlet (*vulva*), where it is continuous with the surface. Not exactly cylindrical, but flattened before and behind, its length is about four inches, its breadth one, but very distensible. It is generally distinguished into the upper vaginal recess (*vaginæ fundus*), inclosing the neck of the womb behind the *os tincæ*, the lower vagina (*vagina propria*), and the vaginal opening (*vulva*).

The *vagina* consists of mucous membrane surrounded by filamentous tissue, a vascular network, and some muscular fibres. The mucous membrane, which is red below, gray above, and not unfrequently marbled, soft and spongy, is disposed in numerous large transverse and semicircular folds (*rugæ*) on the anterior and posterior surfaces. In the recesses of these folds are numerous pores, evidently the source of the mucous viscid secretion which is so abundant on this membrane, during sexual excitation, at the period of parturition, and morbidly in gonorrhœa in the female. On the lateral regions it presents pyramidal eminences (*papillæ*).

The mucous membrane is connected by filamentous tissue to another, which in the vicinity of the uterus is compact, firm, and elastic, and below, towards the orifice, is thinner, and contains a network of numerous communicating vessels, in which the blood is occasionally accumulated in the manner of erection. The lower extremity is inclosed laterally by some muscular fibres (*constrictor vulvæ*), which are believed to have the effect of contracting the *vagina* voluntarily, and by which, when continued, as they occasionally are, to the base of the *labia magna*, women, according to Soemmering, may move these parts. The vaginal membrane is provided with lymphatics connected with those of the pelvis. The nerves, which are numerous, and some of which appear to terminate in the pyramidal eminences, are derived partly from the sacral, partly from the crural trunks.

The *vagina* terminates in the *vulva*, an opening formed within by the *clitoris* before, the *hymen* behind, and the *nymphæ* or *labia parva* on each side; externally by the *mons veneris* before, the *frenum* and navicular *fossa* behind, and the *labia magna* on each side.

The *clitoris* is a small, oblong, conical process, consisting of erectile vessels, covered by mucous membrane, attached to the lower margin of the pubal symphysis. The *hymen* is a crescentic fold of mucous membrane, surrounding the sides and posterior part of the vagina. The small lips or *nymphæ* (*labia parva*) are two crescentic bodies, consisting chiefly of erectile vessels, contained within a duplicature of semimucous membrane. With these the inner surface of the *labia* is continuous; and they consist

Special Anatomy.

chiefly of filamentous tissue, placed between semimucous membrane and skin.

The female breast

Connected with the female ootrophic organs are the breasts or *mammæ*.

The female of the human species has only two breasts; and their position on the anterior and superior part of the *thorax*, on each side of the mesial plane, is a character which, with those of the locomotive apparatus, indicates distinctly the erect biped attitude.

Of a hemispherical or conical shape, the female breast consists of a glandular organ, named the *mammary*, surrounded by adipose tissue, and covered by integuments. It is distinguished into the breast (*mamma*), the nipple (*papilla*, *mammilla*), and a coloured ring of skin (*areola*).

The gland is of a flat, rounded figure, and consists of lobes of white pulpy substance, separated from each other by filamentous tissue, and which may be resolved into granules or *acini* about the size of millet seeds, which again are composed of minute oblong vesicles disposed in a radiating manner. From the granules or *acini* proceed minute tubes named the lactiferous (*ductus lactiferi, tubuli galactophori*), which uniting into larger tubes, varying in number from 20 to 30, terminate in the centre of the mammary gland, behind the areola in conical dilated sacs (*sinus*), varying from one or two to three lines in diameter. These galactophorous ducts, which are larger than in any other gland, are formed of mucous membrane, which extends into the sinuosities, and is at the nipple identified with the skin. Several of the lactiferous tubes are said to originate from the adipose tissue of the breast; but this seems merely to indicate that they communicate with the vessels of this substance. The lactiferous tubes are indistinct before puberty, small in the virgin, and in general in the sterile, and during the intervals of pregnancy, and large only at the close of that period, and during the process of suckling.

The nipple of the female breast is a flat, conical process, the shape of which is well known, consisting externally of skin, with thin delicate corion and epidermis, internally of mucous membrane, and an intermediate network of dilatable arteries and veins mutually and freely communicating. These parts are united by filamentous tissue, which varies in quantity at different periods. But from the vessels now mentioned the nipple derives its property of occasional erection, especially under the influence of mental emotions.

The breast derives its blood from the internal mammaries, the intercostals, and the thoracics or external mammaries, the branches of which penetrate between the lobules of the gland. It has lymphatics, though not more abundantly than any other organ. The nerves are chiefly cutaneous.

The mammary gland is separated from the pectoral muscle by a thick cushion of adipose substance, on which it rests; and it derives a gentle conical elevation from the subcutaneous adipose tissue. The mammary skin is remarkable for the delicacy and softness of the corion.

CHAP. III.—THE PRODUCT OF GENERATION.

The ovum or impregnated germ, the result of the union of the sexes, consists of an embryo or new animal, inclosed in several membranes, and attached to the inner surface of the uterus by a vascular mass.

The fœtal membranes.

Of the membranes, one, the *decidua* (*epichorion*), belongs to the uterine surface; the other two, the *chorion* and *amnion*, belong to the fœtus or embryo. The *decidua* consists of two parts, an external (*decidua vera*), and an internal (*decidua reflexa*); both modifications of albuminous secretion. The chorion, the outer covering of the fœtus, is a thin transparent membrane, covered with villosities on both surfaces, but especially the external. The amnion is a thin transparent membrane, adhering feebly by its external surface to the inner of the chorion, and inclosing a watery fluid, variable in quantity, in which the fœtus, suspended by the umbilical chord, floats.

Special Anatomy.

The umbilical chord.

The umbilical chord (*funis umbilicalis*) consists of, 1*st*, one vein and two arteries, inclosed in—2*d*, a soft, semifluid, gelatinous substance, named from Wharton *gelatina Whartoniana;* 3*d*, the urachus, a ligamentous chord proceeding to the superior *fundus* of the bladder; and, 4*th*, the umbilical sheath (*vagina umbilicalis*). In the early period of uterine life, it also contains part of the intestinal canal, the *vesicula umbilicalis* either partly or wholly, and the omphalo-mesenteric vessels. Of these parts the umbilical veins and arteries, by their connection with the placenta, are the most important. The others our limits allow us merely to indicate.

The placenta.

The *placenta* is a round or orbicular, thick, cake-shaped mass, with two surfaces, a filamento-vascular, attached to the inner surface of the womb, and a smooth membranous one, to which the umbilical chord is fixed. It consists of lobular portions (*cotyledones*), separable from each other, and each of which receives a small artery derived from the uterine trunks, which are much enlarged during pregnancy. The average weight of the *placenta* is 1 pound 2 ounces.

The placenta, according to Dr Hunter (*Anatomical Description of the Human Gravid Uterus*, edit. by Dr Baillie, Lond. 1794), consists of two portions; a *fœtal* or *umbilical*, and a *maternal* or *uterine part*.

The fœtal part is composed entirely of ramifications of the umbilical arteries and umbilical vein. These, dividing with extreme minuteness, are distributed to all parts of the placenta. The branches of the umbilical arteries finally terminate in the umbilical vein, and have no other termination: all the branches of the umbilical vein arise from the umbilical arteries, and have no other commencement.

The maternal part consists of a whitish-coloured substance, which is spread over the outer surface of the placenta in the form of a membrane, and sends off innumerable irregular processes, which pervade its substance as deep as its inner surface. These are everywhere so blended and entangled with the ramifications of the umbilical system, that it is impossible to discover the nature of their union. They are interwoven in such a manner, however, as to leave innumerable small vacuities or cells between them, which communicate freely with each other through the whole mass. The maternal part is full of large and small arteries and veins, none of which are derived from the vessels of the fœtal part, but all from the arteries and veins of the uterus. All the arteries are serpentine, and much convoluted; the larger, when injected, are almost of the size of crow-quills; and, after little or no ramification, they terminate abruptly in the cells already described. This is their only termination. The veins have frequent anastomoses, pass in a very slanting direction, and generally appear flattened; some of them are as large as a goose-quill, but many of them very small; and all arise abruptly from the cells of the placenta. This is their only commencement.

Umbilical arteries.

The umbilical arteries, which are branches of the hypogastric, ascend beside the bladder and before the rectum, approach each other, pass over the *fundus* of the bladder, and reach the navel with the *urachus*. There they alter their direction, and are wound round the umbilical vein, which proceeds from the placenta by the same aperture (the navel) by which the arteries escape. These arteries, which are almost equal in diameter to the hypogastric or posterior iliac, of which they appear to be the continuation, diminish in size after birth, and appear then to be mere branches. Eventually they are obliterated and converted into solid chords, about 1½ inch from their origin.

Umbilical vein.

The umbilical vein, which is larger than both arteries taken together is the common trunk of the veins of the

Special Anatomy.

placenta, from which it proceeds through the umbilical opening or navel, in the folds of the falciform ligament, to the umbilical fossa of the liver, where it divides into two branches, one large, proceeding to the *vena portæ* and liver, another small, into the *vena cava*, known by the name of venous duct or canal (*ductus venosus*). The umbilical vein is distributed chiefly to the left lobe of the liver.

Anatomical peculiarities of the fœtus.

The structure of the fœtus differs in many respects from that of the adult; and these differences depend on the stage which the process of developement has attained. As it is impossible to trace the history of this interesting process within the limits of this sketch, we shall merely specify the principal anatomical peculiarities by which the fœtus is distinguished from the full-grown subject.

A large vascular body, denominated the thymus gland, is found to occupy the anterior *mediastinum*. The kidneys are covered by triangular filamento-vascular bodies, named *renal capsules*, larger than the glands themselves, and supplied with large blood-vessels. The liver is very large, especially its left lobe, and occupies not only the right hypochondriac and epigastric, but the left hypochondriac region. The lungs are compact and of a deep red colour, and sink in water; and the bronchial tubes are collapsed and void of air. In the heart the right and left auricle communicate freely by an oval aperture in the *septum*. The pulmonary artery, rising from the right ventricle, divides, not into two, as in the adult, but into three branches; one on each side, going to each lung, small, and conveying little blood; and one in the middle, proceeding to the aorta, about 9 lines long, named the arterial canal (*ductus vel canalis arteriosus*). The umbilical vein, proceeding to the liver, is distributed by about 15 or 20 branches to the left lobe of that organ. In the horizontal furrow it divides into two branches, one of which goes to the portal vein, the other, apparently the continuation of the trunk, opens into the *vena cava*, under the name of venous duct (*ductus vel canalis venosus*), forming with it an angle acute above, and provided with a valve. The kidneys consist of lobules as numerous as their tubular cones, which indeed these lobules are, separate from each other. The urinary bladder is not within the pelvis, but in the abdominal part of that cavity; and it terminates above in a point, to which a ligamentous process (*urachus*), connecting it to the navel, is attached. In the male, the testicles are contained in the abdomen, often immediately behind the internal aperture. Lastly, till the seventh month the pupillary aperture is closed by a peculiar membrane.

The engravings with which the foregoing article is illustrated have been sufficiently explained by literal or numeral references, in the course of description. We have only to add, that fig. 1 and 2 of Plate XXX., from Soemmerring, are intended to show the important parts at the lower surface of the brain; fig. 3, from the same, the relations of the middle band, vault, and *septum;* and the other two, from Reil, the internal arrangement of the *nucleus*. Plate XXXI., from Scarpa, shows the phrenic nerve, and the thoracic part of the pneumogastric and sympathetic, with the cardiac plexus and nerves. Plate XXXII., from Cruikshank, gives a general view of the arrangement of the lymphatics.

In the foregoing account of the anatomy of the human body, many points have been treated in a manner too short and cursory, considering their importance; and in the attempt to restrain it within due limits, the heads of several have been only indicated. It was the intention of the author to introduce all the new information in microscopical anatomy, which the researches since the year 1832 had furnished. This however, particular circumstances render impracticable. For those who wish to study the subject more minutely, besides the works occasionally mentioned, we refer to the following general systems and treatises.

1. S. Th. Soemmerring *De Corporis Humani Fabrica;* Latio donata, ab ipso auctore aucta et emendata. Tom. i. *De Ossibus*, Trajecti ad Mœnum, 1794. Tom. ii. *De Ligamentis Ossium*, 1794. Tom. iii. *De Musculis, Tendinibus, et Bursis Mucosis*, 1796. Tom. iv. *De Cerebro et Nervis*, 1798. Tom. v. *De Angiologia*, 1800. Tom. vi. *De Splanchnologia*, 1801. This work, which is excellent so far as it goes, and is particularly distinguished for clear arrangement, and distinctness, precision, and accuracy of description, is incomplete. It wants the anatomical description of the eye, the ear, and the generative organs in the two sexes. The first two defects, however, are ably supplied by the author in his *Abbildungen des Menschlichen Auges*, fol. Frankfort, 1801; and *Abbildungen des Menschlichen Hoerorganes*, fol. Frank. 1806.

Of this work a new and greatly enlarged edition, in which the deficiencies above noticed are ably supplied, was published at Leipsic between 1841 and 1844. See historical sketch.

2. *Traité d'Anatomie Descriptive;* par Xav. Bichat, Médicin du Grand Hospice d'Humanitié de Paris, Professeur d'Anatomie et de Physiologie. Tome i. à Paris, 1801; tome ii. et iii. 1802; tome iv. par M. F. R. Buisson, 1803; tome v. par Philib. Jos. Roux, Prof. d'Anatomie, 1803. The death of the author interrupted the publication of this work in the middle of the third volume, the first part of which only is by Bichat; while the sequel of that volume is compiled from the materials left at his death. This constitutes the most accurate descriptive system yet extant; and the strongest proof of its superiority is, that its descriptive portion has been very closely copied in the work of Colquet.

3. *Cours d'Anatomie Médicale, ou Elemens de l'Anatomie de l'Homme, avec des Remarques Physiologiques et Pathologiques, et les Résultats de l'Observation sur le Siège et la Nature des Maladies, d'après l'Ouverture des Corps;* par Antoine Portal, Prof. de Méd. &c. &c. Paris, 1803, tomes cinq. A complete and accurate work.

4. *Handbuch der Menschlichen Anatomie*, von J. F. Meckel, Band i. ii. and iii. Halle und Berlin, 1815. This work was translated into French in 1825, by MM. Jourdan and Breschet.

5. *Traité d'Anatomie Descriptive, redigé d'après l'ordre adopté à la Faculte de Medicine de Paris;* par Hippol. Cloquet, Docteur en Medicine, &c. This is a very good system of descriptive anatomy. In arrangement, M. Cloquet follows that of Bichat; and in description the first volume, and a great part of the second, are copied almost literally from the first, second, and part of the third of that author. It would have been quite as well had this been avowed; for it deprives Bichat of much of his most unquestionable merit, and gives an unfavourable impression of the candour of M. Cloquet. In the sequel of the second, on the vascular system, and the organs of respiration and digestion, the author has availed himself of the materials of Soemmerring.

6. *Elements of the Anatomy of the Human Body in its sound state, with occasional remarks on Physiology, Pathology, and Surgery*, by Alexander Monro, M.D., &c. 2 vols. Edinburgh, 1825.

On the subject of *General Anatomy*, on various details on the anatomical divisions and peculiarities of the Brain, on the minute structure of the Lungs, the Liver, the Kidneys, and other glands, we refer here in general, besides the works mentioned in the close of the historical sketch, to the following treatises.

7. *Elements of General and Pathological Anatomy, presenting a view of the present state of knowledge in these*

Comparative Anatomy.

branches of science, by David Craigie, M.D., F.R.S.E., Fellow of the Royal College of Physicians, Edinburgh, and Honorary Consulting Physician to the Royal Infirmary. Second edition, enlarged, revised, and improved. Edinburgh and London, 1848. Philadelphia, 1851. 8vo, pp. 1072.

8. *The Cyclopædia of Anatomy and Physiology.* Edited by Robert Bentley Todd, M.D., Professor of Physiology and of General and Morbid Anatomy in King's College, London. London, vol. i., 1836; vol. ii., 1839; vol. iii., 1847; vol. iv., 1852; large 8vo.

9. *Elements of Anatomy*, by Jones Quain, M.D. Fifth edition, edited by Richard Quain, F.R.S., and William Sharpey, M.D., F.R.S., Professors of Anatomy and Physiology in University College, London. In two vols. London, 1848.

10. *On the Structure of the Lungs. Researches on the Minute Structure of the Lungs in Man and the Principal Mammiferous Animals.* By M. Le Dr Rossignol. *Edinburgh Medical and Surgical Journal*, vol. lxxii., p. 88. July 1849.

11. *The Human Brain*, by Samuel Solly, F.R.S. London 1847, 8vo., pp. 628.

12. *Plates of the Brain in Explanation of the Physical Faculties of the Nervous System*, by Joseph Swan. London, 1853. 4to.

13. *Archiv für Anatomie, Physiologie, und Wissenschaftliche Medicin.* Herausgegeben von Dr Johannes Müller. Berlin, 1834–1853.

On the subject of *Chirurgical and Topographical Anatomy*, it would be difficult to refer to a more useful work than the following:—

14. *Surgical Anatomy*, illustrated by lithograph coloured engravings; by Joseph Maclise, Surgeon. London, 1849–1851. Second edition, 1853. (D. C.)

COMPARATIVE ANATOMY.

PART I.

ANATOMY OF THE ORGANS OF RELATION.

CHAP. I.—COMPARATIVE OSTEOLOGY.

Red-Blooded Animals only can be said to possess that assemblage of bones denominated skeleton; and as in these the most constant part is the vertebral column, it furnishes the general character of Vertebrated. The shells of the Mollusca and the *Crustacea* have been generally regarded as a species of internal skeleton; and in the circumstance of affording mechanical support and external protection, they indeed resemble the skeleton of the Vertebrata. But neither in mode of developement nor in chemical constitution can they be regarded as of the same nature. Hence it is only in the vertebrated classes that it is requisite to study the peculiarities of the skeleton.

Bones generally.

In general characters the bones of the Mammalia resemble those of the human subject. Like them, they are white, firm, elastic, and incompressible. They consist also of compact and reticular or cancellated tissue. In the lower animals the latter kind of structure is in general coarser and looser than in man; and in the Cetacea especially the cavities are large. In the carnivorous animals the compact structure is exceedingly dense, and gives the bone much greater weight than in other animals. In the Cetacea also the acoustic or lithoid portion of the temporal bone is of a marble hardness.

The bones of the Mammalia may, like those of man, be distinguished, according to their mechanical form, into long, flat, and short bones. Though the first class in general possess a medullary canal, this cavity is imperfect or wholly wanting in the bones of the Cetacea and Amphibia.

The cavities denominated *sinuses* are much more completely developed in several of the Mammalia than in the human skeleton. In the pig these cavities extend into the occipital bone; in the elephant they not only give the frontal bone extraordinary protuberance, but they extend into the parietal, temporal, and even the occipital bones, and contribute much to augment the volume of the head. In the ox, deer, and sheep, they communicate with the cavity of the horns.

The bones of Birds are in general whiter, firmer, and smoother than those of the Mammalia; and they consist of a firm, compact substance, which is elastic and hard in the bones of the trunk, and extremely brittle in those of the extremities. With the exception also of some of the thin, flat bones, as the sternum, they consist of thin, compact walls, inclosing large capacious cavities, which contain not marrow, but air, and which communicate by one or more minute holes with the windpipe and lungs. While these cavities, which may be regarded as the most perfect and advanced form of sinuses, diminish considerably the weight of the whole skeleton, by the density and completely cylindrical shape, they rather augment the strength. In the chick, and at birth, the bones are homogeneous and without cavities; afterwards they contain marrow; and eventually this disappears and gives place to air.

The bones of the Reptiles are not remarkable in any respect, unless in being void in general of medullary cavity. The absence of this canal was originally observed by Caldesi, and afterwards by Cuvier, in the tortoise; by Troja in the bones of the frog and toad; and by Carus in those of the turtle. In the crocodile, however, and in several of the lizard family, they are large and distinct. The bones of Reptiles also are less firm than those of Birds and Mammals.

The bones of Fishes are remarkable for great softness, flexibility, and elasticity. Those of the lamprey, shark, ray or skate, and sturgeon family, are soft, flexible, sectile, of a bluish white colour, translucent, and so elastic that a cutting instrument forced into them is speedily retruded by the resilient nature of the bony matter. From these characters, the bones of these families have been regarded as cartilaginous, and the fishes themselves have been distinguished by this character. (Pisces cartilaginei, pisces chondropterygii.) In the other fishes, the bones, though softer than those of Mammals, Birds, and Reptiles, present a greater degree of firmness and solidity, are whiter and more opaque, and are much less sectile, than those of the cartilaginous division. As in this respect, therefore, they approach the genuine bone of the Mammals, these are distinguished as fishes with osseous skeletons. (Pisces ossei.)

The bones of both classes of fishes consist of a large quantity of gelatine, with a small proportion of phosphate

Comparative Anatomy.

of lime. In the osseous fishes, however, the latter substance is most abundant.

The colour of the bones of fishes, though in general whitish gray, is observed to vary in certain genera. In the gar-pike (*esox belone*), for instance, they are green, and in the viviparous blenny (*blennius viviparus*), the sand launce (*ammodytes tobianus*), and two species of *labrus* (the *l. lapina* and *æruginosa*), they assume a green colour after boiling. The causes of these varieties in colour are unknown.

SECT. I.—OSTEOLOGY OF THE MAMMIFEROUS ANIMALS.

Plate XXXIV. fig. 1.

The skeleton of the MAMMALIA bears a general resemblance to that of the human subject, in the construction, shape, and disposition of its component pieces. Distinguished, like that, into head, trunk, and extremities, we recognise the importance of the trunk, and especially of the spine, in the different classes of mammiferous animals.

The spine.

The spine consists of separate vertebræ, which are conveniently distinguished, as in man, into *cervical*, *dorsal* or *costal*, *lumbar*, *sacral*, and *coccygeal* or *caudal*.

Cervical vertebræ.

The number of cervical vertebræ is the same in animals with the longest and shortest necks,—in the horse, camel, and giraffe, and in the mole and ant-eater. They are always seven. The only exception is observed in the *Ai* or three-toed sloth (*bradypus tridactyla*), which has 9 cervical vertebræ (Cuvier); and an apparent exception is presented in the dolphin and porpoise, in which the first two are consolidated into one; and in the cachalot or large-headed whale, in which the last six, sometimes the whole seven, are united or ankylosed. The last six are also united in the ant-eater and manis (Cuvier). Even in this state, however, the traces of the original separation are distinct.

In the ape the cervical vertebræ are distinguished from those of man chiefly by the spinous processes being stronger and not bifid, and in their bodies being projected more over each other before, so as to support the head more perfectly. In the ZOOPHAGA the transverse processes of the cervical vertebræ are flattened from behind backwards, and those of the *atlas* are very large, both for supporting the head and giving attachment to the strong muscles employed in defence, attacking prey, or bearing it off. For the same purpose the spinous process of the *axis* is very prominent, while the others are short and directed towards the head. In the mole and shrew the cervical vertebræ, which are void of spinous processes, are simple osseous rings, which move easily on each other, probably to facilitate the frequent motions requisite in these animals in burrowing. In the hog the cervical transverse processes are compressed and broad before, so as to appear double. In the elephant the cervical vertebræ have short single spinous processes, and the bodies projecting over each other as in the ape. In the Ruminants the length of the spinous processes diminishes as the neck is elongated. Thus they are almost wanting in the camel and giraffe, in which the arched neck is much retro-flected; and the same peculiarity is recognised in those of the horse.

From these facts it results that the length of the neck depends not on the number, but on the longitudinal extent, of the cervical vertebræ.

Dorsal vertebræ.

The dorsal, thoracic, or costal vertebræ are distinguished by forming the central fixed basis of the ribs; and their number depends on that of the latter class of bones, which is very variable. The number of costal vertebræ varies from 11, which is that of the Chinese monkey, common bat, armadillo, helmet-headed dolphin (*delphinus globiceps*), and Gangetic dolphin, to 23, which is that of the *Unau* (*Bradypus didactylus*). The most common number is 12, which is that not only of man, but of the ourang-outang, silky monkey (*simia marikina*), patas (*s. patas*), maimon (*simia maimon*), macaca (*simia cynomolgus*), baboon (*s. sphynx*), magot (*s. inuus*), mandrill (*s. maimon*), pongo (*s. pongo*), macauco (*lemur catta*), vampyre, great and horse-shoe bat, colugo (*galeopithecus*), shrew, hare and rabbit, agouti, flying squirrel, mouse and field rat, and camel and dromedary. The next most frequent number is 13, which is that of the mole, white bear, civet, the cat tribe (*felis*), the dog, wolf and fox, the *didelphis* tribe, the cavy, guinea pig and paca, the mouse tribe, excluding the two exceptions already mentioned, the long-tailed *manis*, the stag, the antelope genus, the goat, sheep, and ox, and the dolphin and porpoise. The number is 14 in the gibbon, coaïta, and weeping monkey, in the howling ape (*simia beelzebul*), the *tarsius*, the brown bear, raccoon and coati, the weazel *genus*, the porcupine, hog, and giraffe. It is 15 in the lori, hedgehog and tenrec, in the badger, pangolin, and seal. The number is 16 in the glutton, hyena, ant-eater, American lamantin, and *megatherium*. In the horse, quagga, and dugong, they are 18; in the rhinoceros 19; in the Indian elephant and tapir 20; and in the *Unau* or two-toed sloth 23, which, as already stated, is the greatest number yet known.

In the ape family the dorsal vertebræ resemble those of the human subject, but their spinous processes are long, and erect in the macaca and magot. In the bats, instead of spinous processes, which are wanting, there are minute tubercles. The want of these, however, in sundry species, leaves the column comparatively smooth behind. In the proper quadrupeds these processes are larger, straighter, and stronger, as the head is weighty or supported on a long neck, in order to give attachment to the strong yellow cervical ligament. This peculiarity is very distinct in the giraffe, camel, ox, rhinoceros, and elephant. In the dolphin they are straight, and smaller than those of the loins.

Lumbar vertebræ

The lumbar vertebræ vary in number still more, perhaps, than the cervical and dorsal; and this variety may occasionally be traced to the greater or less distinctness with which the sacral and coccygeal are distinguished. The smallest number is 2, which is that of the two-toed ant-eater, *ornithorhyncus*, and American lamantin; and the greatest 9, which is that of the lori. The most frequent number is 7, which is that of the greater part of the monkeys, the macauco, the great bat (*noctula*), the hedgehog, shrew, raccoon; the tiger, panther, puma, and cat, in the feline *genus*; the wolf and fox in the dog; the hare and rabbit; the whole murine *genus* except the hamster; and in the camel and dromedary. The next number in frequency is 6, which is that of the horse-shoe bat, the colugo (*galeopithecus*), the white and brown bear, the coati, the weasel genus, the civet, the lion, among the feline, and the dog among the canine genus, the didelphis and cavy *genera*, the hamster, the stag, antelope, goat, sheep, ox, horse, and quagga. The gibbon, coaïta, *Ai*, *Echidna* or *Ornithorhyncus hystrix* of English zoologists, six-banded armadillo, and dugong, have only 3 lumbar vertebræ; the ourang-outang, pongo, and howling ape, 4; the vampyre bat 4; the hyena, armadillo, *Unau*, and tapir, 4; the jocko, tarsier, and common bat, 5; the badger and glutton, the porcupine, beaver, pangolin, long-tailed manis, hog, giraffe, gazelle, chamois, and seal, all 5; and the agouti and flying squirrel have 8.

In the QUADRUMANA and ZOOPHAGA generally the outer side of each posterior articular process presents an apex turned backward, so that the anterior articular process of the next vertebra is locked between two eminences, which confine its movement much. Though this apex is found

Comparative Anatomy.

in the Rodentia, it is there shorter; and the arrangement is wanting in the other tribes. The size of the transverse processes indicates the strength of the loins,—a fact which is evinced especially in the instance of the horse, porpoise, &c.

Sacral vertebræ.

The number of sacral vertebræ is still more various, even in the species of the same genus. Thus, while in several of the ape *genus*, in the lori, in the vampyre bat, the colugo (*galeopithecus*), the coati, and two of the didelphis, there is one sacral vertebra only, most of the apes have *sacra* consisting of 2, 3, 4, 5, or 6 pieces; the majority of other animals have 3 sacral vertebræ; the hedgehog, porcupine, guinea pig, paca, hare, tiger, several of the murine genus, the ant-eater, rhinoceros, camel, dromedary, chamois, goat, sheep, and ox, have 4; the elephant has 5; the *Ai* 6; the *Unau* 7; and in the mole, white bear, and quagga, they also amount to 7. The frequency of the three sacral vertebræ in the lower animals shows that Galen, who ascribes only 3 to the human subject, must have derived this inference from the former.

These vertebræ are in the mammalia narrower than in man, and their direction forms with the spine, instead of receding backwards, a straight line; an arrangement evidently connected with the horizontal position of the former. The shape of the sacrum in the lower mammals is that of an elongated triangle; and it is further remarkable, that in those species which occasionally assume the erect attitude on the hind leg, as apes, bears, and sloths, the width of the sacrum is proportionally greater. The sacral spines, which are short in man and the ape, become longer in the Zoophaga, and form a continuous ridge in the rhinoceros, most ruminants, and especially in the mole. In the vampyre bat the sacrum forms a long compressed cone, the extremity of which is united to the ischial tuberosities, without sustaining a coccyx. The seal has two sacral bones; but the Cetacea, *e. g.* the dolphin and porpoise, are void both of sacrum and coccyx.

The coccygeal bones constitute the tail of the lower animals, and in many instances they are extremely numerous. The smallest number is 3, which is that of the magot (*simia sylvanus, pithecus, et inuus*) or Barbary ape; and the greatest yet known is that of the ant-eater, in which they amount to 40, and the long-tailed manis, in which they amount to 45. Next to these may be placed that of the coaïta 32, the baboon 31, the phalanger (*didelphis orientalis*) 30, the marmoset (*didelphis murina*) 29, the pangolin 28, the silky monkey (*simia rosalia*) and black rat 26, the weeping monkey and howling ape 25; the panther, mouse, dormouse, and elephant, 24; the lion, beaver, water-rat, Norway rat, and field-rat, 23; the flying-cat, puma, cat, dog, marmot, and rhinoceros, 22; the otter, 21; the Chinese monkey, raccoon, civet, hare, and rabbit, 20; the tiger and wolf, 19; the macauco, glutton, marten, fat dormouse, dromedary, giraffe, and quagga, 18; the tarsier, shrew, camel, and horse, 17; and other genera and species, without any determinate order, descending so low as to 9, 8, 7, 6, and 4. The quilled duckbill (*echidna, ornithorhyncus hystrix*) has only 12 caudal vertebræ, while the common one (*ornithorhyncus paradoxus*) has at least 20. The gibbon and vampyre bat are the only mammiferous animals, excepting the Cetacea, in which there are no coccygeal bones. It sometimes happens that a monkey or opossum loses a portion of its tail, when the truncated end is converted into a knotty excrescence, sometimes carious, always different from the taper point of the last coccygeal vertebra; and in this case it is difficult to determine the exact species.

In the Cetacea, in which the absence of *pelvis* affords no mark to distinguish the lower vertebræ into lumbar, sacral, and coccygeal, those below the dorsal may be regarded as *lumbo-coccygeal;* and their number is estimated by deducting that of the cervical and costal from the total number. The following table, which shows the number of the costal, the lumbo-coccygeal, and the total number of vertebræ, indicates that their number varies much in various *genera* of this family.

	d.	l.c.	t.		d.	l.c.	t.
Lamantin	16	24	46	Porpoise	13	40	60
Dugong	18	28	46	Narwal	12	35	54
Dolphin	13	47	67	Hyperoodon	9	29	45
Tursio	13	38	58	Cachalot or White Whale	14–15	39	60
D. Globiceps	11	37	56				
D. Griseus	12	42	61	Greenland Whale	15	37	59
D. Gangeticus	11	28	46	Rorquhal	14	31	52

In general, however, if we reckon the first 2, 3, or 5 vertebræ after the costal as lumbar, it may be said that the caudal vertebræ of the Cetacea vary from 22 or 25, which are the numbers respectively in the lamantin and dugong, to 34, 38, and 42, at which they may be estimated in the dolphin. We shall see that, in the dugong at least, we are guided in this estimate by the rudimental bones of the pelvis.

The coccygeal or caudal vertebræ of the Mammalia may be distinguished into two kinds; those which contain a canal in continuity with that of the vertebral column and sacrum, and those in which the pieces are solid. The first, which are next the sacrum, have articular, transverse, and spinous processes, distinct in proportion as the animals move their tails. The latter are generally prismatic in shape, diminish in size towards the extremity, and have only slight tubercles for muscular attachments. Animals with prehensile tails, as the American ape (*sapajous*), have above, at the base of the body of each vertebra, two small tubercles, between which pass the tendons of the flexor muscles. By means of this mechanism these animals can twine the tail round the branch of a tree with sufficient force to support the weight of the body.

The Mammalia with long mobile tails have often two or three small supernumerary bones placed on the lower surface of the junctions of several of the coccygeal vertebræ, from the 3d or 4th to the 7th or 8th. These sesamoid bones give attachment to muscles. In the beaver, which employs its tail as a trowel, the transverse processes are remarkable for size, while the lower spinous processes are larger than the upper ones,—an arrangement which enables it to depress the tail forcibly when it beats the ground.

The chest.

The shape of the chest in the Mammalia varies in general as the clavicles are present or wanting. In animals provided with clavicles, as the Quadrumana, bats, the squirrel, beaver, mole, ant-eater, hedgehog, and sloth, the shape of the chest approaches to the human, or is conoidal, and flattened before and behind. In those void of clavicles it is compressed laterally, from the smaller incurvation of the ribs; and the sternum makes a remarkable prominence, so that the transverse or intercostal diameter is less proportionally, and the sterno-vertebral is greater proportionally, than in man and the claviculated animals. In the long-legged animals, as the giraffe and those of the stag kind, this prominence of the sternum is sufficient to give it a keel-like appearance (*thorax carinatus*). In the carnivorous animals the chest presents its greatest longitudinal extent.

The sternum.

The ribs.

The number and shape of the ribs varies in the different tribes. In number, indeed, the ribs always correspond with that of the costal vertebræ. Thus, in the Quadrumana, Zoophaga, Rodentia, Edentata, and Ruminantia, they vary from 12 to 15 pair, with only three exceptions, the glutton, hyena, and ant-eater. In the Chinese monkey, common bat, and armadillo, they are a pair less than in

Comparative Anatomy.

man. While the quilled duckbill (*echidna, ornithorhyncus hystrix*) has only 15 ribs, the common duckbill (*ornithorhyncus paradoxus*) has 17; the horse and quagga have 18, the rhinoceros 19, the elephant and tapir 20, and in the *Unau* or two-toed sloth they amount to 23, which is the greatest known number. On the whole, the most prevalent number is 13. In the carnivorous animals they are narrow and dense in structure. In the herbivorous they are large, broad, and thick. In the armadillo the two first ribs are large compared with the others. In the two-toed ant-eater, which has 16 pairs, they are so broad that they are imbricated over each other like the plates of a corslet, and render the parietes of this animal's chest exceedingly solid. In the two species of duckbill (*ornithorhyncus paradoxus* and *hystrix; echidna* of Cuvier), the true ribs, in number 6, consist of two portions—a long or vertebral joined to the spine, and a short or sternal attached to the sternum. These portions are united by cartilage, so as to resemble the ribs of birds. The 9 or 10 false ribs terminate before in broad, flat, oval plates of bone, which are mutually connected by elastic ligaments.

The sternum, which is broad in the ourang and pongo, is narrow in the other species of ape, and consists of seven or eight pieces. In the vampyre and all the bat family it is narrow, but presents before or below rather a prominent azygous ridge or keel (*carina*), and an anterior extremity, broad on the sides, like a T, for receiving the clavicles. In the mole the clavicular extremity of the *sternum* is continued before the ribs, and is flat on the sides for receiving the two short clavicles. In the hog the sternum is broad behind and narrow before. In the rhinoceros, horse, and elephant, it is prolonged before and flat on the sides. In the CETACEA it is broad and thin, especially before.

Cranium.

Though the QUADRUMANA have 8 cranial bones, the sphenoid often consists of two portions, one forming the orbitar wings and the anterior clinoid processes, the other the temporal or large wings, the posterior clinoid processes, and the basilar fossa. The two parietal bones are early united into one in the CHIROPTERA and the other ZOOPHAGA, in which, however, the frontal remains biparted by a middle suture. The temporal tympanum is separated from the rest of the bone by a suture, which is seldom obliterated in the feline, canine, and *viverra* genera. The temporal tympanum is also separate in the RODENTIA, and the frontal ununited. The parietal is united in some, as the hare, the porcupine, *cabia*, marmot, rat, and squirrel; separate in the mouse, fat dormouse, and rabbit. The frontal and parietal bones of the elephant are early united with the other cranial bones, and form a vault without trace of suture. In the hog, tapir, and *hippopotamus*, the two parietal bones form one piece, while the frontal bone is biparted; and though in the rhinoceros both are biparted, the frontal is early united into one portion. The sphenoid bone of the animals of this tribe long consists of two pieces, one forming the orbitar wing; the other the temporal wings, which, it is to be further observed, are the smallest, in opposition to their proportional dimensions in man. In the Ruminants and SOLIDUNGULA the frontal remains long parted by its middle suture; but the two parietals are represented by a single bony vault. The tympanum is always distinct from the temporal bone. In the seal and walrus the parietal and the frontal consist of two pieces. The lamantin has only one bony arch, representing the two parietal and the squamous part of the temporal bones, while the temporal tympanum is detached from the rest of the bone. In the other CETACEA the parietal bones are at an early period united to the occipital and temporal bones, so that the five form one solid portion. The auditory or pyramidal bone is always detached from the temporal, and adheres to the cranium by soft parts only. The sphenoid is not only long separate, but consists of several portions.

Though, among the QUADRUMANA, the cranium of the ourang-outang approaches that of man in shape, it differs nevertheless in the connections of the constituent bones. The temporal wing of the sphenoid bone is very narrow, does not reach the parietal, and touches the frontal only by its upper extremity, so that the temporal bone is partly articulated with the frontal. The temporal suture is not imbricated, but serrated. The same mode of connection is observed in the mandrill, macaca (*s. cynocephalus*), magot, and guenon (*Cercopithecus*), or tailed monkey tribe. In the American monkey the temporal wing of the sphenoid touches neither the frontal nor the parietal bones; but the temporal bone is articulated directly with the malar by its flat portion. In the American monkeys the frontal bone does not touch the temporal wing of the sphenoid, and the parietal is articulated to the malar. In the howling ape (*simia beelzebul*) the connections are as in man.

Connections.

The connections of the cranial bones are in the ZOOPHAGA the same as in man. In the RODENTIA the sphenoid is joined to the frontal and temporal, without touching the parietal; and the orbitar and temporal *fossæ* are very small. In the armadillo, pangolin, and sloth, the connections are as in the RODENTIA; but in the ant-eater the parietal bone, continued below the cranium, is united to the sphenoid at the posterior part of the orbito-temporal *fossæ*.

In the elephant, though the cranial bones are at an early period consolidated into one, the auditory is always distinct from the temporal bone. In the hog, tapir, rhinoceros, and hippopotamus, the sphenoid is united to the parietal bone, and its temporal wings occupy a small space only of the orbitar and temporal fossæ. The orbitar wings, though larger, appear small externally. The auditory bone, though distinct, is, however, united by its base to the margin of the auditory canal of the temporal bone. The sphenoid of the ruminants is articulated, as in man, with all the cranial bones; but its orbitar wing, which is extensive, is principally concealed within the cerebral cavity, and covered by the orbital part of the frontal bone. In the CETACEA generally, all the sutures which remain after early life are squamous or imbricated.

The outline of the frontal bone in the ourang-outang is more irregular than in man, and the orbitar arches are less surbased. In the American monkeys its outline is triangular, and terminates in a point towards the vertex. In the others of this family (*Simia*), this bone is almost elliptical, and the orbitar arches are nearly straight; and in the whole family these arches form, as in man, the anterior border of the frontal bone, in consequence of the narrowness of the root of the nose. In the makis it begins to widen, and the eyes become oblique,—a circumstance which gives their frontal bone a rhomboidal shape.

The frontal bone in the ZOOPHAGA, and in all the subsequent MAMMALIA, except the CETACEA, forms an irregular prismatic or cylindrical surface with three faces—a superior, bounded before by the muzzle, behind by the cranial convexity and two lateral, descending into the orbitar and temporal *fossæ* on each side. The hedgehog, mole, shrew, ant-eater, some of the *phocæ*, the morse or walrus, and the rhinoceros, have no proper orbitar arches; and the frontal bone, though broad behind, is contracted and nearly cylindrical between the orbits. In the hippopotamus, the ruminants, and the one-hoofed animals, it enlarges, and forms a vault over each orbit. Lastly, in the CETACEA it is narrow from before backward, resembling a fillet stretched across the cranium, but descends beneath the maxillary bones to form the floor of the orbit.

Comparative Anatomy.

The parietal bones of the ourang-outang differ from those of man only in their temporal margin being nearly straight. Those of the ape are narrower, and become more oblique-angled as the cranium is flattened. In the Zoophaga and Edentata they are almost rectangular. The single parietal of the Rodentia is nearly quadrilateral; but it is sometimes flat, sometimes rounded, sometimes surmounted by a crest. Of the single parietal bone of the ruminants, that of the stag, most of the antelope *genus*, the sheep and the goat, is broad, and sends on each side a narrow process into the temporal *fossa* before the occipital arch; in the camel it is narrower, and bears a longitudinal crest; and in the ox and *antilope bubalus* it is placed behind the occipital crest, and resembles a fillet surrounding the back of the head transversely. In the Solidungula the single parietal is nearly quadrilateral, and placed before the occipital crest.

The occipital bone.

The occipital bone in the lower mammalia is remarkable for five characters. 1. The proper occipital surface, instead of being oblique or horizontal, and inferior or basilar, becomes vertical and posterior. 2. The plane of the occipital hole forms with that of the orbits an angle constantly diminishing, becomes parallel to the orbitar plane, and at length crosses it above the head. 3. The plane of the occipital condyles, instead of being transverse and horizontal, becomes oblique, and at length vertical. 4. The basilar or cuneiform process is not only horizontal, but forms with the occipital a right angle. And, 5. The mastoid process, which in man and the ape forms part of the temporal, belongs in the other mammalia to the occipital. In the polar bear, however, the mastoid process constitutes part of the temporal bone.

From the 1st, 2d, and 3d characters, it results that the head of quadrupeds is not balanced on the spine, but is suspended by muscles, tendons, and ligaments, especially the strong cervical, which connects the occipital spine to the spinous processes of the cervical and dorsal vertebræ. This ligament, therefore, though feeble and indistinct in man, is strong, particularly in quadrupeds with heavy head or long neck, in order to counteract the disadvantage of the long lever. It is strongest in the elephant, and is almost wholly ossified in the mole—a condition requisite for the burrowing faculty exercised by that animal.

The temporal bone.

The temporal bone is naturally distinguished in the Mammalia into two parts; a flat or proper temporal, corresponding to the squamous part of the human temporal bone, and the pyramidal, acoustic, or auditory, corresponding to the pyramidal or lithoid portion of the human subject. The first only, which is proper to the scull, claims attention here. In the ourang-outang and most of the genus *simia* it forms a trapezium with the longest side above, and the height of which varies with that of the scull. In the American apes it is smallest in this direction. In the Zoophaga the proper temporal bone is as in the ape. Being narrow in the Rodentia behind, it is a little rounded in the short-muzzled Edentata, the Ruminantia, and Pachydermata.

The ethmoid is, strictly speaking, the olfactory bone, and shall be mentioned under the organs of sense. The sphenoid, among other offices, may be regarded as the essential ophthalmic bone.

The facial bones.

The facial bones of the lower Mammalia differ from those of man; first, in the number of separate pieces; and, secondly, in the form and proportional horizontal extent.

Intermaxillary bones.

The difference in number consists in each superior maxillary bone being divided into a maxillary bone proper, and an anterior or labial portion; which being interposed between the proper maxillary, are commonly denominated the intermaxillary (*ossa intermaxillaria*). As it bears also the superior incisors, it is named by Haller the incisive bone (*os incisivum*); but since it is found not only in the ruminants, which, excepting the camel, are void of incisors, but in the Edentata and Cetacea, this denomination is less applicable than the former. It may be doubted whether these should be regarded as additional bones, as they are generally represented by zootomists; for they are in truth merely the incisive or anterior portion of the superior maxillary bones. In other respects, the difference between the human and the animal superior maxillary bone is, that in the former each bone is in one piece, in the latter it is in two. Even in the human fœtus the trace of the separation may be recognised; and we have seen it in the human scull some years after birth. Conversely, it is early obliterated in some quadrupeds. Thus, though distinct in the ourang-outang seen by Cuvier, it was not found by Tyson or Daubenton, and is wanting in one preserved in the Hunterian museum. In a young specimen of the jocko also, noticed by Cuvier, no trace of the intermaxillary suture was observed. It appears also to be wanting in the perforated bat, the horse-shoe bat, and the three-toed sloth.

Mutually united on the mesial plane, the intermaxillary bones are united to the maxillary by sutures, which pass from the outer angles of the latter, near the incisive holes, towards the palate, where they intersect. In form and size it varies in the different orders and genera. Small in many of the Zoophaga and the walrus, it is large in the Rodentia, in the hippopotamus, porpoise, and cachalot, and prominent in the wombat. In the duckbill it consists of two unciform portions, united by a broad intermediate cartilage.

Elongation of the face.

The peculiarity of the animal face consists in the horizontal elongation of the two jaw-bones. In the monkey tribe this elongation is trifling; and all that is remarked is, that the palate and maxillary bones are more elongated in proportion to their height, and that their anterior part, instead of being vertical, is more or less inclined forwards. The degree of this elongation, which differs in different *genera*, may be estimated by the acuteness of the facial angle.

Interorbital region.

The narrowness of the interorbital space is another character of the animal countenance. In the *guenon* and American ape it is a mere *septum;* but in the ourang-outang, magot, and howler, it is larger, by reason of the nasal *fossæ* ascending to this height. From these the face of the Zoophaga is distinguished by the following circumstances. 1. The breadth of the ascending maxillary processes throws the orbits to the sides; 2. these orbitar surfaces form the anterior wall instead of the floor of the orbit; 3. the malar bone is united neither to the frontal nor to the sphenoid bone, and forms only the zygomatic arch and the lower margin of the orbit; 4. the orbit, closed neither behind nor below, communicates freely with the temporal *fossa;* and, 5. the palate bones are much elongated and form a considerable space of the internal wall, to which the ethmoid bone does not contribute. In the Rodentia the interorbital space is still larger, by reason of the size of the intermaxillary bones throwing the maxillary backwards and to the sides, where they form the inner orbitar wall, in which the palate bones occupy only a small space. The anterior wall is formed by a process of the maxillary, which contributes to form the zygomatic arch, while the malar is suspended in the middle between the process and that of the temporal bone. Very similar is the face of the elephant, except that the height of the *alveoli* from the tusks, thrusting the nose upwards, and shortening its bones, alters entirely the expression of the head of this animal.

In the sloth, in which the face is short in proportion to

Comparative Anatomy.

the scull, the malar bone attached to the maxillary only, is not united to the zygomatic process of the temporal. In the long-muzzled EDENTATA, in which the face is conoidal, the maxillary bones extend to the orbits, and are separated by a broad lacrymal bone, while a long palate bone forms the inner wall of these *fossæ*. The zygomatic arch, which is interrupted in the ant-eater and pangolin, is completed in the Cape ant-eater and the armadillo. In the tapir and rhinoceros the maxillary bone passes beneath the orbit; and the nasal bones form a sort of vault, which supports in the first animal the trunk, and in the second the horn.

In the CETACEA the maxillary and intermaxillary bones form a sort of flattened beak, distinguished into four parallel bands, of which the maxillary, which are external, alone bear teeth in three genera, provided with the latter organs. The nasal *fossa* is a vertical opening before the cranium, surrounded before and laterally by the intermaxillary bones. The maxillary ascend in the same manner, and cover that part of the frontal bone which forms the orbitar vault, but do not themselves contribute to the formation of this cavity. The nasal bones are two minute tubercles implanted on the frontal bone above the narrow aperture. The malar is in the shape of a style, suspended by cartilages beneath the orbit; and the latter cavity is completed behind by a process of the frontal, which joins the zygomatic of the temporal bone, and below which the orbitar and temporal *fossæ* communicate.

Orbits.

The direction of the orbits, the shape of their base or facial border, and their relation to the temporal *fossa*, are important circumstances in the animal face and cranium. In the *simiæ* the angle of the orbitar axes is rather smaller; and the shape of the margin, which is quadrilateral in the jocko, becomes oval in the ourang-outang and American monkeys. The angle of the axes enlarges in the other Mammalia; and the base or anterior margin becomes nearly circular in the ZOOPHAGA, RODENTIA, EDENTATA, and PACHYDERMATA; but the arch is incomplete behind. In the *Ruminants* and SOLIDIPEDA, however, in which it is also circular, the border is complete. In the CETACEA the orbitar vault is semicircular, their axes are rectilineal, and there is no floor.

In the human scull the junction of the malar bone with the frontal and sphenoid completes the orbit externally, and prevents it from communicating with the temporal *fossa*; and the same arrangement is observed in the *simiæ*. In the CARNIVORA, RODENTIA, EDENTATA, and PACHYDERMATA, however, in which the malar bone is united neither to the frontal nor the sphenoid, the orbit is not only incomplete on the external posterior border, but communicates freely with the temporal *fossa*. In the Ruminants is observed an arrangement intermediate between that of the QUADRUMANA and that of the CARNIVORA. The malar bone, united to the frontal, completes the orbitar ring; but as it is not united to the sphenoid, it allows the orbits and temporal *fossæ* to communicate. The orbit of the mole is so superficial, that it can scarcely be said to exist.

The lower jaw.

The lower jaw of the mammiferous quadruped differs from that of man chiefly by the following circumstances. The triangular flat surface which constitutes the chin, and which is most distinct in the Caucasan race, begins to become faint in the negro, and is altogether lost in the monkey tribe. In the ourang-outang, indeed, the animal character of the lower jaw appears distinct in the vertical convexity of the anterior arch of the jaw, and the retreating of its lower margin. In the lower QUADRUMANA the anterior maxillary arch is still more retreating, and the maxillary *rami* form a more acute and elongated angle. These animal characters are still more conspicuous in the CARNIVORA, most of the PACHYDERMATA, Ruminants, SOLIDUNGULA, and RODENTIA. The ascending *ramus* also becomes short in the PACHYDERMATA and several of the CETACEA, more so in the ZOOPHAGA, and is almost extinct in several of the RODENTIA, for instance the paca, beaver, and porcupine, and the armadillo, ant-eater, and duck-bill, among the EDENTATA. In the ZOOPHAGA, however, in which the prehensile and masticatory muscles are large and powerful, the *ramus* becomes broad, and its coronoid process is extensive. The angle which the *ramus* forms with the body of the jaw, and which is almost right in the adult human subject, becomes obtuse in the lower animals, nearly at the same rate at which the *ramus* disappears; and indeed the transition of the angle into a straight line implies the disappearance of the *ramus*. This, therefore, is the character in the EDENTATA and CETACEA, in which there is neither *ramus* nor coronoid process, after these parts have been seen for the last time in the amphibious MAMMALIA.

When the mammiferous cranium is considered generally, and the relative direction and proportion of the cranial and facial part of the head examined, we recognise more distinctly the characters by which the lower orders of that class are distinguished from man. This character consists in the position of the occipital bone and hole, the position and direction of the facial bones in relation to the frontal, the elongation of the former, and large size which they present in relation to the cranial.

In the human subject, it has been already observed, the position of the occipital bone is oblique and horizontal, and the plane of the occipital hole is horizontal, while its position is anterior. In most quadrupeds, while the bone assumes a vertical position, the hole becomes posterior, and its plane vertical or oblique, in proportion as the face is elongated. The plane of the occipital hole forms with that of the horizontal a considerable angle, which Daubenton undertook to determine, by drawing one line through the plane of the aperture, and another from its posterior margin through the lower edge of the orbit. (*Mém. de l'Acad. des Sciences de Paris*, 1764, p. 568.) In the horse this angle is about 90°, while in the ourang-outang it is only 37°, and in the *lemur* 47°. In other respects, however, it furnishes an imperfect result, since in most quadrupeds which differ very much it ranges between 80° and 90°.

Camperian line and angle.

The direction of the face in relation to that of the cranium, determined according to the method of Camper, furnishes more accurate results. While in the human subject it varies, according to the races, from 70° to 80°, in the ourang-outang it is only 65°; in the American and long-tailed monkeys about 60°; in the macaca and baboon about 45°; and, lastly, in the mandrillo, the most vicious and ferocious of the monkey tribe, only 30°. In some species in which the ear is elevated and the guttural *fossa* deep, for instance in the pongo and *alouate* or howler, the small size of this angle does not indicate proportional elongation of muzzle; and to rectify this inconvenience, it is requisite to draw the basilar line of the facial angle parallel to the base of the nostrils. With this modification, however, the Camperian line admits of correct application to the human race and QUADRUMANA only, in which the frontal sinuses are small and not prominent. In quadrupeds, for instance the carnivora, several of the ruminants, and in the elephant, the frontal sinuses are so large and prominent as to affect the results given by the facial angle very materially. In other orders, again, for instance the RODENTIA and the morse, the nose occupies so much space that the cranium is inclined backwards without its walls being free before; and it is impossible to know where the facial line passes. These, therefore, must be measured by the inner surface. Lastly,

Comparative Anatomy.

in the CETACEA the pyramidal elevation of the cranium above an elongated but flattened face renders the facial line much more vertical than it ought to be. The following measurements show the angle subtended by a line drawn parallel to the base of the nostrils, and another passing by the anterior margin of the *alveoli*, and touching the convexity of the cranium, whether the point of contact be concealed by the face or not.

European infant	90°	Mastiff, tangent within	31
European adult	85	Hyena, without	40
European aged	75	Ditto, within	25
Negro adult	70	Leopard, within	28
Young ourang-outang	67	Hare, within	30
American monkey	65	Marmotte, within	25
Java monkey	57	Porcupine	23
Young mandrill	42	Pangolin	39
Coati	28	Babiroussa	29
Pole-cat	31	Ram	30
Pug-dog	35	Horse	23
Mastiff, tangent without	41	Dolphin	25

Method of Cuvier.

Aware of the imperfect results obtained in this method of measurement, Cuvier proposes to estimate the relative proportion of the cranial and facial part of the head, by comparing the respective areas exhibited by a longitudinal and vertical section of both. In this section the area of the cranium is to that of the face sometimes in a ratio of majority, sometimes of minority, occasionally of equality.

In the European the area of the cranial section is about four times that of the face, excluding that of the lower jaw. In the negro the cranial area remaining the same, that of the face augments about one fifth, whereas in the Calmuck it augments only one tenth. In the ourang-outang the proportion is still less. In the American ape the facial is almost half the cranial area. The ratio is that of equality in the mandrill and most of the CARNIVORA, except the varieties of short-muzzled dogs, as the pug, in which the facial is rather less than the cranial area. In the RODENTIA, PACHYDERMATA, Ruminants, and SOLIDUNGULA, the facial is larger than the cranial area. Among the RODENTIA, in the hare and marmot, it is a third larger; in the hedgehog double; in the Ruminants almost double; in the pig a little more than double; nearly triple in the hippopotamus; and almost four times in the horse. In the morse and elephant the face is rendered large by the height of the *alveoli;* and it may be regarded as augmenting the organs of the senses. The cranium of the CETACEA is very convex, and the face very flat, and the proportional area of the latter is thereby diminished. The facial area of the dolphin may be a third larger than the cranial.

The outline of the cranial section in the human subject is oval, that of the facial section forms a triangle, with the longest side contiguous to the cranium, and the smallest without, while the angle formed by the latter with the third side or palate is the facial. In the lower animals, this triangle, which may be named the *facial*, becomes so much elongated, that the cranial side, which is the longest in man, becomes the shortest of the three in the *cynocephalus* and mandrill, and continues so in the other quadrupeds.

The pelvis.

The basin (*pelvis*) of the MAMMALIA in general agrees with that of man in forming a part common to the trunk and the lower extremities. It differs, however, altogether in the direction which it takes, which is obliquely backwards, with its anterior opening or brim forwards and downwards, and in the bones being smaller and much narrower; both of which characters are connected with its not being used in the lower animals to oppose the gravitating weight of the abdominal and pelvic *viscera*. In the apes, most similar to man, the coxal bones are much elongated; and in the ZOOPHAGA, their superior or ilial part is not much broader than their pubal. In the Ruminants, the PACHYDERMATA, and SOLIDUNGULA, the ilial portions again become broad; and in the elephant and rhinoceros especially, this width, combined with the length of the ilio-pubal *rami* and the concave abdominal surface, concurs to give the *pelves* of these animals the prodigious capacity by which they are distinguished. The *pelvis* of the amphibious MAMMALIA differs from that of the ZOOPHAGA only in being narrow and elongated, and in the *pubis* being thrown behind. In the ant-eater, mole, and shrew, the pubal junction is open as in birds; and in the two latter *genera*, the bones are so narrow that the sexual and urinary organs are placed without its circumference. In the sloth *genera*, e. g. the *Ai* and *Unau*, the pelvis is wide, the cotyloid cavities turned upwards, and the ischial tuberosity is united with the sacrum, so as to convert the ischiatic notch into a hole. This sacro-ischial junction is also observed in others of the EDENTATA, as the ant-eater and armadillo, and in the *phascoloma* (*didelphis ursina*). The marsupial animals present two minute bones, one on each side, connected by movable articulation to the pubis, and which are employed to sustain the mammillary pouch (*marsupium*) or nipple-bag, in which the young are reared after exclusion from the *uterus*. These bones, which are distinguished by the name of marsupial (*ossa marsupialia*), are oblong and flattened. Lastly, in the CETACEA, in which the pelvic extremities are wanting (Plate XXXIV. fig. 2), the pelvis is also so far deficient, that instead of consisting of the sacrum and coxal bones, it is represented by a small bony appendage, suspended in the soft parts on each side of the anus, and which, meeting at angles on the mesial plane so as to form a bone like the letter V, are merely a rudiment of the ischial bones.

The shoulder of the MAMMALIA generally differs from that of man by the absence or the proportions of the collar-bone, and by the shape of the *scapula*.

The collar-bone.

The collar-bone exists in the QUADRUMANA nearly as in man; but it is wholly wanting in the three orders of UNGULATA—PACHYDERMATA, the Ruminants, and the SOLIDUNGULA—and in all the CETACEA. Between these extremes it is found in various forms in the intermediate orders of the UNGUICULATA. Among the ZOOPHAGA it exists in the CHIROPTERA, especially the bats proper, in which it is strong and large; the INSECTIVORA, as the hedgehog, shrew, and mole *genera;* and in the didelphis or opossum among the marsupial animals. In the others of this order, as the bear, raccoon, coati, weasel, otter, dog, cat, and seal, the collar-bone is represented by clavicular bones, suspended among the muscles, touching neither the sternum nor acromion; and in some species it is altogether wanting. The RODENTIA may be distinguished into two subdivisions, as they are provided with or void of collar-bones. The first comprehends the squirrel, beaver, and mouse, with the *helamys*, marmot, and aye-aye or cheiromys *genera*. The second consists of the porcupine, hare, and cavy *genera*, as the guinea-pig and paca, in which the collar-bone is rudimental only, suspended among the soft parts. It exists in most of the EDENTATA, as the sloth, armadillo, ant-eater, and the gigantic fossil animal named *megatherium;* but it is wanting in the pangolin, and was believed to be wanting in the *echidna* and duckbill till Cuvier demonstrated its existence. In the CETACEA there is no vestige of collar-bone.

From these facts it results that the clavicle exists in all animals, the fore legs of which are frequently or habitually protruded, either to seize, as apes and the RODENTIA; or to fly, as bats; or to dig and burrow, as the mole; or to rake the ground, as the hedgehog and ant-eater. In the mole particularly, the collar-bone, instead of being long, is

a broad, thick, short, quadrangular bone; and while it is connected to the acromion by a ligament, it is articulated to the humerus by a large facette. The collar-bone of the *echidna* and *ornithorhyncus* is very singular. It consists of a broad central bone, surmounted by two transverse branches spreading out on each side, so as to give the whole bone some resemblance to the letter T, but sinuated so as to make the diverging branches like the Greek *υ*. In young animals this bone consists of three portions. The two diverging branches are genuine collar-bones, and may be regarded as a bifurcated bone; while the middle is supported on the sternum, and has articulated to each side a part of the *scapula*, corresponding to the coracoid process. The collar-bone, indeed, is a powerful buttress, which prevents the arm-bone from being thrust too much forward.

The shoulder-blade.

Of the shoulder-blade or *scapula*, which is present in all red-blooded animals with thoracic extremities, and hence in all the Mammalia, the principal point is to remark the varieties which its shape presents. Though in man, most of the Quadrumana, the Chiroptera, and the elephant, the vertebral margin or base of several authors on human anatomy is the longest, it becomes the shortest in most quadrupeds, especially those which, like the Ruminants and the Solidungula, have long legs and narrow chest. In most of them, also, this margin, instead of being straight, is rounded, as in the Carnivora and Rodentia. In the Carnivora without collar-bone, the hedgehog and *didelphis*, the acromion is less prominent; there is another eminence directed backwards, almost perpendicular to the spine. The coracoid process, also, which is present in the Chiroptera, the hedgehog, and *didelphis genus*, is wanting in most of the zoophagous tribe. In the hare the acromion terminates in a long slender process, rising at right angles and bending backwards, which may be named the *recurrent*. In the Ruminants and Solidungula, not only are this and the acromion, but even the coracoid, wanting. The *scapula*, again, of the hog and rhinoceros is remarkable for the disappearance of the spine at the glenoid angle; while from its middle proceeds a prominent process towards the costal or inferior margin. In the mole the scapula is long and narrow, like a cylindrical bone, placed parallel to the spine,—an arrangement which, together with the shortness and thickness of the clavicle, already mentioned, is evidently connected with the burrowing habits of this animal. Lastly, in the *echidna* and *ornithorhyncus*, which in so many characters of organization approach the Amphibia on the one side, and the Birds on the other, the scapula is a single sinuous bone, attached by one extremity to the sternum and middle part of the clavicular bone, with the other loose; and in the middle an articular cavity, in which the head of the humerus is placed, and which evidently corresponds to the glenoid. In this instance, therefore, the clavicle and *scapula* may be regarded as united into a single bone.

The humerus.

The *humerus*, which exists in all the animals with thoracic extremities, undergoes considerable variations. In the lower animals generally it is much shorter than in man; and it is invariably shorter in proportion as the *metacarpus* is elongated. Thus, in animals with what is named a *cannon* bone, that is, one metacarpal, as in the horse and the ruminants, the *humerus* is so short that it is concealed in the soft parts as far as the cubit. In the Cetacea it may be said to attain its maximum of brevity. In the bat and sloth it is long in proportion to the rest of the body.

The *humerus* of the mole is perhaps the most extraordinary of all those of the mammiferous animals. Not only is it articulated with the *scapula* by a small head, but it is connected with a facette of the clavicle by another belonging to the great tuberosity, and between which and the head is a deep pit. The crest of the small tuberosity is so large, that it represents a square placed vertically, so that the *linea aspera* is above. The rest of the body of the bone, which is very short, is arched above, so that the cubital extremity is directed upwards. From this arrangement it results that the cubit is elevated above the shoulder while the palm is turned downwards,—a disposition necessary for the burrowing habits of the animal.

Radius and ulna.

In the *simiæ* the *radius* and *ulna* are arranged as in man, except that in the *cynocephalus*, mandrill, magot, and guenon, the coronoid process of the *ulna* is narrower, and the radial facette deeper. In the other Mammalia the *ulna* very generally disappears or becomes rudimentary only. In the bat family and the colugo (*galeopithecus*) the *ulna* is wanting or is represented by a slender style placed below the radius. These animals are therefore destitute of the power of pronation and supination. In the Zoophaga, the *radius* and *ulna*, though separate, are void of rotatory motion; and the *olecranon* is compressed, and continued farther back than in man. In the Pachydermata the *radius* is before and the *ulna* behind, and, though distinct, there is no rotation. In several of the Rodentia, for instance the marmot, porcupine, &c. the coronoid process is small, and in others, *e. g.* the cavy, hare, and mouse family, it is altogether effaced. In the Ruminants the *ulna* is united immovably to the radius; and in the Solidungula it is represented by an *olecranon* adhering to the posterior surface of that bone. In the Cetacea, though both bones are present, they are much flattened.

Carpus.

The *carpus* of the ape *genus* contains one bone more than that of man, situate between the pyramidal and large bone, and which seems to result from the trapezium being divided into two parts. Conversely, in the Zoophaga, but especially in the dog, cat, hedgehog, shrew, bear, and seal, the scaphoid and semilunar are united into one large bone. Those which have a vestige of thumb, as the hyena and glutton, have the trapezium very small. The mole has not only 9 carpal bones, as the ape, but a large sickle-shaped bone, which is attached to the radial margin of the fore paw, and which gives it the shape proper to the habits of the animal. The toes are further very short. Of the Rodentia, the hare resembles the ape; but in the beaver, marmot, squirrel, and cat, the scaphoid and semilunar make one bone; while in the porcupine the supernumerary bone is between the pisiform and metacarpal of the fifth toe. In the two-toed ant-eater there are only 6 carpal bones, 4 in the first row and two in the second; in the three-toed sloth there are only 5, 3 in the first row and 2 in the second; the pangolin has 7; the cachecame 8 and a rudimental small toe; the elephant 8, 7 wedge-shaped and one elongated, corresponding to the pisiform; and the other Pachydermata 8. In the rhinoceros, which has only 3 toes, the trapezium only is wanting; but there is a supernumerary bone on the margin of the scaphoid, and on that of the unciform, as in the porcupine. The first range consists, in the Ruminants and Solidungula, of 4 bones; in the former, excepting the camel, the second consists of 2, and the latter of 3. Those of the Cetacea, which are much flattened, are 3 in the first row and 2 in the second.

Metacarpus.

The Mammalia generally have as many metacarpal bones as toes, that is, never fewer than 3 or more than 5, with the exception of the Ruminants, in which these bones are in early life consolidated into one named the *cannon* bone. In animals which walk on the tips of the toes, or which use them as organs of prehension, the metacarpal bones are lengthened to nearly double; and hence in all these animals the *metacarpus* is erroneously named the fore leg, and therefore it has been imagined, that in several

Comparative Anatomy.

of our domestic animals the different parts of the lower extremity are articulated in opposite directions to those of man. Thus the fore leg of the horse, deer, sheep, and dog are in truth the *metacarpus* of these animals; and what is vulgarly named the fore knee or *cannon* bone of the horse, is actually the *carpus* or wrist-joint. It is therefore convex on the dorsal, and concave and inflected on the palmar aspect, exactly as the *carpus* of the human subject.

In the three-toed sloth, the three bones of which the metacarpus consists are mutually consolidated at the base and with the rudiment of a fourth toe. In the Cetacea, the metacarpal bones, which are much flattened, are also mutually united.

Fore toes.

In the Mammalia generally, if we include imperfect or rudimental phalanges concealed in the skin, there are never fewer than 3, nor more than 5. The Unguiculated animals generally have 5, perfect and imperfect. The character of the perfect fore toe or finger is to consist of 3 rows or phalanges, excepting the first of the radial side, which has only 2. In the Quadrumana this is separate, and opposable to the other toes, constituting a thumb, and giving this tribe of animals a prehensible organ entitled to the epithet of hand. It is, however, shorter and less perfect in other respects than the genuine thumb of the human hand. In the *coaïta* (*simia paniscus*) it is converted into a rudimental bone, concealed under the skin.

In the Zoophaga, which have no power of grasping minute objects, the thumb or first toe is parallel to the others, and, though equal in length to these in the ursine family, it is shorter in the *mustela*, *viverra*, canine and feline *genera*. In the latter, which have the power of erecting the claws, to prevent them from being blunted in walking, the shape of the middle and unguinal phalanx is remarkable. The former is triangular prismatic, with two lateral and a plantar or palmar inferior surface. The third or unguinal phalanx is shaped like a hook, consisting of two parts. One, directed forwards, sharp and pointed, receives the nail or claw, in a long groove like a sheath. The second part of the hook, which is behind, rises vertically from the lower part by which it is articulated, and is produced into two processes, to which are attached the erecting muscles of the claw, which are flexors of the phalanx.

Among the Rodentia there is a perfect but short thumb in the hare, beaver, and jerbois; a two-phalanx but concealed one in the squirrel, mouse, and rat family, porcupine, paca, agouti; and a one-phalanx concealed one in the cavy, guinea-pig, marmot, &c. In the Edentata the number of fore toes varies much; in the *Tamanoir*, and *Tamandua* or four-toed ant-eater, the thumb-toe is obliterated; in the *Ai* or three-toed sloth, both that and the fifth toe are obliterated; and in the two-toed ant-eater, and *Unau* or two-toed sloth, these, with the second toe also, are obliterated.

The elephant has 5 perfect toes, all concealed under the thick, callous hide of the foot. In hoofed animals with 4 toes, for instance the hog, tapir, and hippopotamus, the thumb-toe is in the shape of a small rudimental bone.

In the Ruminants the single metacarpal bone (Cheselden's figure of the Deer, Plate I.) is articulated with two digital phalanges, which constitute one of the distinguishing characters of this order—the cloven foot. In some genera, at the root of these two perfect toes are two small bones, often covered with horn, which represent two other toes. The last or unguinal phalanx is always trilateral in shape. In the horse and the Solidungula generally, the two lateral toes are represented only by two bony styles, named the splint bones, situate on the two sides of the metacarpal or *cannon* bone. The three phalanges of the single toe which constitutes the foot are distinguished as the *pastern bone*, which is the first phalanx; the *coronet*, which is the middle or second; and the *coffin* bone, which is the third or unguinal phalanx, which has the shape of the hoof, rounded before, convex above, and flat below. To the back of the pastern joint are connected two sesamoid bones; and to the coffin bone is attached another, named the shuttle bone. In the Cetacea, all the phalanges, which are flattened, and often cartilaginous, are united in the fin or paddle.

The fore cannon bone.

Thigh-bone.

The thigh-bone, which is single in all the classes, follows the type of that of the human frame in general figure and parts. In the Mammalia it is, however, proportionally shorter, and its length diminishes as that of the *metatarsus* augments. In the Ruminants and Solidungula, for instance, it is so short that it is concealed by muscles against the belly; and hence it is too often overlooked and confounded with the leg. In other respects the general characters are, that it is not arched; that, excepting in the bear and some of the *simia* genus, *e. g.* the ourang-outang, it is shorter than the leg-bones; that its neck is very short, and more perpendicular to the *axis* of the *diaphysis* than in man; and that the great trochanter is raised above the head, which is directed inwards. In the *simiæ* it is quite cylindrical, and void of *linea aspera*. In the tapir the middle part is found flattened; and at the external margin there is a prominent crest, terminating in an unciform process. In the rhinoceros the great trochanter and the unciform process are so elongated as to unite almost, and form a hole between them and the *diaphysis*. The unciform process is observed also in the horse, beaver, and armadillo. The thigh-bone of the seal is so short, that the half of its length consists of the two articular extremities.

Leg-bones

Though the leg-bones of the Mammalia bear a general similitude to those of man, the *tibia* alone is constant; and the *fibula*, after becoming unusually slender, and changing its position from the outside to the posterior part of the tibia, is converted into a mere appendage, and at length disappears entirely. Thus, though it is distinct, and occupies its usual position in the *simiæ*, in the Chiroptera it is extremely slender; and since the *femora* are directed backward, the *fibulæ* are turned towards each other. In several of the Edentata, for instance the phatagin, armadillo, and sloth, it is large, curved, and remote from the *tibia*. In the dog family and the Rodentia it is altogether behind the *tibia*. In the mole and murine *genus* it is consolidated to the lower third of the *tibia*, leaving an empty trilateral space above. In the rhinoceros, elephant, and hog, the *fibula* is flattened and united to the whole length of the *tibia*. In the ruminants it is represented by a small bony appendage, placed on the outer margin of the *astragalus*, below the *tibia*, and forming the external or fibular ankle. Lastly, in the horse and Solidungula, the *fibula* is reduced to a styloid rudimental process, which is firmly consolidated in the adult animal to the upper part of the *tibia*.

Between the *tarsus* of man and that of the other Mammalia the following are the principal differences.

The tarsus.

In the *simiæ* the fibular facette of the *astragalus* is nearly vertical, and the tibial is very oblique; and the *calcaneum* wants the tuberosity, except in the pongo. In the ordinary bat family the calcaneum is elongated into a styloid process, concealed in the substance of the membranous ubiform expansions; but in the roussette (*pteropus*) the tuberosity projects beneath the foot.

In the Rodentia the calcaneum is produced considerably backwards, while the scaphoid, which consists of two parts, forms a tubercle on the sole. Among the Edentata the three-toed sloth is peculiar in having a tarsus,

consisting of four bones only, the *astragalus*, *calcaneum*, and two cuneiform bones, the first of which is articulated not only with the *tibia*, *fibula*, and *calcaneum*, but with the large cuneiform bone, without any intermediate scaphoid bone. Its connection with the *tibia* is by means of a convex articular surface, which rolls on the external part of the tarsal end of the *tibia*. From this mode of articulation it results that the foot of the sloth admits neither of being elevated nor depressed, but simply of performing lateral motions of adduction and abduction, to which it owes the power of clasping the trunks of trees and climbing, but which renders progression difficult and laborious.

The hog has a scaphoid with three ordinary cuneiform bones, and a rudimental great-toe bone beneath the first. In the tapir and rhinoceros there are only two cuneiform bones. All the animals already enumerated have the same number of metatarsal bones as of toes.

In the Ruminants the cuboid and scaphoid bones are united, unless in the camel, in which they are distinct. At the outer margin of the pulley of the astragalus is a bone which represents the lower head of the *fibula*, and which is farther articulated to the upper surface of the os calcis. In this side also there are only two cuneiform bones, which are united in the giraffe. The two metatarsal bones are always united, as in the *metacarpus*, into one, which forms a posterior cannon bone. The Solidungula resemble the camel in this, that the scaphoid is distinct from the cuboid bone, and that there are two cuneiform bones, while the peroneal rudiment and the corresponding articular surface of the calcaneum are wanting. The metacarpal are also consolidated into a single piece, named the hinder *cannon bone*, each side of which is provided with a minute bony style.

Third cannon bone.

Hind toes.

The toes of the Quadrumana and the Marsupialia are longer than those of man; but the great toe is shorter than the others, and its metatarsal bone is susceptible of separation and opposition, as the thumb or thumb-toe of the hand. Hence Cuvier, in his first classification, distinguished the latter by the name of *Pedimana*. The *Aie-aie* among the Rodentia appears to possess the same faculty. Among the Zoophaga the great toe remains always conjoined with and parallel to the others; and in the canine and feline genera it is obliterated. Among the Rodentia, that of the beaver is nearly equal to the other toes; those of the marmot, porcupine, and the murine genus, are shorter; in the paca it is almost obliterated; it is reduced to a single bone in the Cape gerboa; and the leporine genus have no trace of it. In the cavy, agouti, and guinea-pig, the great and small toes are each reduced to one bone. In the gerboa (*mus jaculus*) and alactaga (*mus sagitta*) the three middle metatarsal bones are united into a single one similar to the cannon bone of the Ruminants and Solidungula; and while the two lateral toes are distinct, though short, in the former animal, they are obliterated altogether in the latter.

Among the Edentata, the ant-eater, *orycteropus*, pangolin, and armadillo, have five toes, of which the great is the shortest in all. In the sloth the great and small toe are reduced to one small bone. The other metatarsal bones are united at their base. The toes have only two phalanges, of which the unguinal are the largest.

In the subsequent families the metatarsal bones deserve particular attention. In the elephant and Pachydermata, their tarsal extremity has a flat surface, and the phalangeal consists of a convex tubercle, which presents below a prominent line in the middle of the bone. In the Solidungula this line is above and below both. In the Ruminants, in which the cannon bone consists of the two metatarsal bones, the line of union is represented by a deep line like the tract of a saw. The elephant has 5 perfect toes; the hog 4; the tapir and rhinoceros 3; the Ruminants have two perfect toes on one metatarsal bone, and two small ones attached behind its base. The Solidungula have one perfect toe, and two imperfect, which are reduced to a single styloid bone. In these animals the body is supported in walking by the last or unguinal phalanx alone; and hence the term *foot* is not of the same import as in the human subject and animals similarly constructed. While indeed man supports his person in progression on the *os calcis* and the posterior or metatarsal phalanges, in the other mammiferous animals the former bone touches not the ground, but is always elevated above it a considerable height. All the zoophagous or unguiculated animals, excepting the plantigrade, support themselves chiefly on the unguinal and middle phalanges both of the fore and hind foot; and neither the posterior *phalanges* nor the *calcaneum* touch the ground, as is easily demonstrated on observing the gait of the hedgehog, dog, fox, cat, or similar individuals of the same family. The animals distinguished by the name of Plantigrade are believed to support themselves on the entire foot. But though the foot is certainly spread on the ground more freely than in those already mentioned, by the bear, glutton, badger, and others, it appears that not the heel, but the *metatarsus*, is allowed to touch the ground in progression. In the Ruminants and Solidungula, as already mentioned, the only part of the foot which is applied to the ground is the unguinal phalanx; and it is well known that the horse supports himself on the plantar surface of the coffin bone only.

Lastly, in the Amphibious Mammals, while the extreme brevity of the *humerus* and *femur* unfit them for progression on land without extreme awkwardness and difficulty, the expanded shape and oblique position of the metacarpal bones and phalanges, the length of the *tibia* and *fibula*, and the greater length of the first and last than the middle metatarsal phalanges, all concur to give these animals great facility in swimming. (Cuvier, *Ossemens Fossiles*, tome v. partie i. septieme partie.) In the Cetacea, again, while the total want of pelvic extremities renders motion on land quite impracticable, the fin-like disposition of the metacarpus and metacarpal phalanges, with the great strength of the lumbar, and the length of the coccygeal vertebræ, peculiarly qualify them for locomotion in the waters.

SECT. II.—OSTEOLOGY OF BIRDS.

Plate XXXIV. fig. 3.

The number of vertebræ of which the different regions of the spine consist, is not less variable in Birds than in the Mammalia. Some idea of these variations may be formed from the number exhibited in the following table by Cuvier.

Spine.

Species.	Vertebræ of Neck.	Vertebræ of Back.	Sacral Vertebræ.	Coccygeal Vertebræ.
Vultur. Vulture	13	7	11	7
Falco fulvus. Eagle	13	8	17	8
—— *haliaëtus.* Bald buzzard	14	8	11	7
—— *buteo.* Buzzard	11	7	10	8
—— *nisus.* Sparrow hawk	11	8	11	8
—— *milvus.* Kite	12	8	11	8
Strix bubo. Eagle owl	13	7	12	8
Strix ulula. Brown owl	11	8	11	8
Muscicapa grisola. Fly-catcher	10	8	10	8
Turdus merula. Blackbird	11	8	10	7
Tanagra tatao. Tanagra	10	8	9	8
Corvus corone. Crow	13	8	13	7
—— *pica.* Magpie	13	8	13	8
—— *glandarius.* Jay	12	7	11	8
Sturnus vulgaris. Starling	10	8	10	9
Loxia coccothraustes. Grosbeak	10	7	12	7
—— *pyrrhula.* Bullfinch	10	6	11	6

Species.	Vertebræ of Neck.	Vertebræ of Back.	Sacral Vertebræ.	Coccygeal Vertebræ.
Fringilla domestica. Sparrow...	9	9	10	0
——— *carduelis.* Goldfinch...	11	8	11	8
Parus major. Titmouse.........	11	8	11	7
Alauda arvensis. Lark..........	11	9	10	7
Motacilla rubecula. Red-breast	10	8	10	8
Hirundo urbica. Swallow.......	11	8	11	9
Caprimulgus Europæus. Goat-sucker.........................	11	8	11	8
Trochilus pella. Colibri..........	12	9	9	8
Upupa epops. Hoopoe...........	12	7	10	7
Alcedo ispida. King's fisher...	12	7	8	7
Picus viridis. Woodpecker.....	12	8	10	9
Ramphastos. Toucan............	12	8	12	7
Psittacus erithacus. Parrot......	12	9	11	8+
Columba œnas. Stockdove......	13	7	13	7
Pavo cristatus. Peacock.........	14	7	12	8
Phasianus colchicus. Pheasant	13	7	15	5
Meleagris gallopavo. Turkey...	15	7	10	5
Crax nigra. Curassow bird. Hocco.........................	15	8	10	7
Struthio Camelus. Ostrich......	18	8	20	9
——— *Casuarius.* Cassowary...	15	11	19	7
Phœnicopterus. Flamingo.......	18	7	12	7
Ardea cinerea. Heron............	18	7	10	7
—— *alba.* Stork.................	19	7	11	8
—— *grus.* Crane.................	19	9	12	7
Platalea Aïaïa. Spoonbill........	17	7	14	8
Recurvirostra. Avoset..........	14	9	10	8
Charadrius pluvialis. Plover...	15	8	10	7
Tringa vanellus. Lapwing......	14	8	10	7
Scolopax rusticola. Woodcock...	18	7	13	8
——— *arquata.* Curlew........	13	8	10	8
Hæmatopus. Oyster-catcher...	12	9	15	0
Rallus crex. Rail................	13	8	13	8
Fulica atra. Coot................	15	9	7	8
Parra. Jacana.....................	14	8	12	7
Pelicanus onocrotalus. Pelican...	16	7	14	7
——— *carbo.* Cormorant...	16	9	14	8
Sterna hirundo. Sea swallow...	14	8	10	8
Larus. Gull.......................	12	8	11	8
Procellaria. Petrel...............	14	8		8
Anas cygnus. Swan.............	23	11	14	8
—— *anser.* Goose................	15	10	14	7
—— *bernicla.* Bernacle.........	18	10	14	9
—— *boschas.* Duck..............	14	8	15	8
—— *tadorna.* Sheldrake.......	16	11	11	9
—— *nigra.* Black diver.........	15	9	14	7
Mergus merganser. Merganser	15	8	13	7
Colymbus cristatus. Grebe......	14	10	13	7

In this table the most remarkable circumstance is the great number of cervical vertebræ, which are much more numerous than in the Mammalia. They vary from 9, the number in the sparrow, to 23, which is that of the cervical vertebræ of the swan. The most common number is 11, which is that of 10 *genera*. The next most frequent is 12, 13, and 14, which are equally the numbers of 9 *genera*. The next is 15, which is that of 8; 10 occurs in 6, 18 in 4, and 16 in 3. In the stork and crane they are 19.

The next remarkable circumstance is, that the dorsal or costal vertebræ are greatly fewer than in the Mammalia, never exceeding the number of 11, and being more frequently about 7 or 8. Thus, while they are 11 in the cassowary, swan, and sheldrake, 10 in the goose, bernacle, and grebe, and 9 in the sparrow, lark, humming-bird, parrot, crane, avoset, oyster-catcher, cormorant, and black-diver, they are 7 or 8 in all the other *genera*, and only 6 in the bullfinch.

There are no lumbar vertebræ strictly so named, for those which extend from the chest to the tail are consolidated into one piece with the iliac bones. The tail, which is short, consists of from 7 to 9 vertebræ.

The part most variable in proportional length is the neck. It is so much longer as the feet are elevated, except in some of the swimmers, in which it is greatly longer, because they require to seek their food below the surface of the waters on which they float.

The bodies of the cervical vertebræ are articulated not by plane facettes, which would admit obscure motion only, but by portions of cylinders, which allow extensive motion. The 3d, 4th, or 5th superior vertebræ allow of anterior inflection only, and the others of posterior inflection. This gives the necks of birds an alternate serpentine inflection; and it is by rendering the two arches, of which this curvature consists, straight or convex, that the animal elongates or shortens his neck. The articular processes of the superior vertebræ are directed upwards and downwards; those of the lower are turned anteriorly and posteriorly.

Instead of transverse processes, the cervical vertebræ of birds are provided with a tubercle above, and the anterior extremity of which terminates in a narrow style, descending parallel to the body of the vertebra.

Only the most superior and inferior vertebræ have distinct spinous processes, and these have anterior as well as posterior ones. The middle ones have before two crests, which form a half-canal, and behind a tubercle, often bifid, or, when they are elongated, two rough lines. The atlas, which is articulated with the occipital bone by a single facette, has the shape of a minute ring.

Back.

As the neck of birds is movable, the back is fixed. The spinous processes of these vertebræ are in mutual contact, and they are connected by strong ligaments. Most of these processes are generally consolidated into a single continuous crest, extending along the whole back. The extremities of the transverse processes terminate in two *apices*, one directed forwards, the other backwards; and occasionally they are consolidated into a continuous mass like the spinous. That this arrangement is requisite for the trunk to remain fixed during the violent motions which take place in flying, is rendered probable by the fact, that in birds which do not fly, as the ostrich and cassowary, the spinal column retains its mobility.

The last dorsal vertebræ are often placed on the crest of the iliac bones, and they are then united, as the lumbar, on the large piece of the iliac bones, from which it results that the number of vertebræ can often be estimated in no other mode than by that of the holes of the nerves which issue from the chord.

Caudal vertebræ.

The caudal vertebræ are most numerous in the species which move the tail with most energy; for instance, the magpie and swallow. They have spinous processes below as well as above, and very long transverse processes. The last of all, to which the pinions are attached, is longest, and has the shape of a ploughshare or a compressed quoit. In the cassowary, which has no visible tail, the last bone is conical; in the peacock, on the contrary it has the shape of an oval plate, situate horizontally.

Cranium.

It was early observed by the original zoologist and traveller Pierre Belon, that the *crania* of birds were void of sutures; and that in a few only were these lines of distinction into separate bones recognised. The explanation of this peculiarity is found in the history of the ossification of the head in young birds, which shows that the cranium consists at that period of separate bones, corresponding in number and situation to those of quadrupeds. Thus, there are two frontal bones, which are continued forwards to form the vault of the orbits; two small parietal bones behind the frontal; a temporal bone on each side of the scull; a sphenoid united to the occipital, even in subjects in which the other sutures are distinct; or a spheno-occipital bone, which is early united with the temporal.

These sutures, however, are distinctly seen only in

Comparative Anatomy.

young birds and those recently hatched; for the bones are very early united, and in the adult bird the cranial sutures are invariably obliterated. Thus, in the domestic fowl and turkey the scull is one piece; and the only trace of suture that remains is a linear depression in the middle of the frontal bone, indicating the original formation in two halves. In the recently hatched bird, also, the sphenoid is separated from the occipital bone by a transverse suture, extending from the one ear to the other. The occipital bone is at the same time a ring, consisting of four parts; a superior, two lateral, and an inferior which is small. The sphenoid, which forms the greater part of the base of the cranium, is nearly trilateral, with a small anterior process, to which the palatine arches are articulated. It has no pterygoid processes, and does not touch the posterior aperture of the nostrils. The temporal bone, though void of zygomatic process, has a pointed style, which contributes to form the posterior margin of the orbit. The frontal bone, after covering part of the cranium, is continued forwards in a broad, thin plate, which forms the vault of the orbits, while these cavities are separated by a thin vertical bony plate which descends at right angles from the frontal bone, and is connected behind with the sphenoid. The long eminences observed on the heads of the cassowary, curlew, pintado, and some species of hocco, are produced from this supra-orbital part of the frontal bone; and their interior, which consists of loose *diploe*, communicates with that of the same bone.

Facial bones.

The face in birds is rarely so firmly consolidated as the cranium. It is composed of two lacrymal bones, forming the anterior margins of the orbits, and united on the mesial plane; two nasal bones anterior to the lacrymal; two bones corresponding to the superior maxillary, and forming the external lateral parts of the upper half of the bill; two inter-maxillary bones; two anterior palate bones, corresponding to those of the MAMMALIA; two posterior palate bones corresponding to the pterygoid processes of the sphenoid; and the lower jaw a paraboloid bone, consisting of two *rami* united before, where they are covered by the horn of the lower half of the bill. Besides these, there is in the whole class an irregular-shaped bone, common to the cranium and lower jaw, and connecting these two together. This bone, which has been rather improperly named the square, quadrangular, or quadrilateral bone (*os quadratum*), consists of a body with curvilinear hollow margins, terminating in two elevated and rather pointed processes, one of which is connected with the cavity named *tympanum*, while the other, projecting into the orbit, affords attachment to several muscles. The anomalous character of this bone has perplexed several of the most distinguished zootomists; and while Geoffroy gives it the name of *os Tympano-styloideum*, Spix considers it analogous to the annular process of the temporal bone, which in the human fœtus is separate; and Carus regards it as representing the *incus*, to which it bears a remote resemblance in shape and in one of its connections.

The quadrilateral bone.

Maxillary bones.

Both *maxillæ* are void of teeth; but the hard, horny matter of the bill covering the margins and extremities of each jaw, and constituting the mandibles (*mandibula*), is manifestly constructed to perform for BIRDS what teeth do for the MAMMALIA. But the most remarkable peculiarity of the facial bones of this class is, that the upper jaw admits of more or less motion. In the majority of instances this is effected by the jaw being united to the cranium by means of thin, flexible, elastic, bony plates; but in the parrot family the upper jaw is entirely distinct, and is connected by a proper articulation.

The base of the palatine surface of the upper jaw is divided into 4 branches, which diverge backwards. The two external ones, which correspond to the zygomatic arches of the MAMMALIA, and which are very slender, are articulated to the quadrangular bone which moves on the temporal before the ear. The two intermediate ones, which have been already stated to correspond to the pterygoid processes, and which are parallel, are placed beneath the septum of the orbits, and are articulated by their posterior extremities with a small bone, variable in shape, but named *omoid* by Herissant, which is also articulated with the quadrilateral. From this arrangement results a singular species of broken lever, not dissimilar to the parallel joint of the piston and lever of the steam-engine, and the effect of which is, that whenever the lower jaw is depressed by its proper muscles, it necessarily causes the quadrilateral bone to perform a slight rotatory motion, in consequence of which, by means of the omoid bone, the upper jaw is at the same time elevated on the elastic plates; and as soon as the lower jaw is raised, the elasticity of these plates forces down the superior one.

The upper jaw is immovable in a few instances only, and of these the *calao* or rhinoceros bird is one.

Sternum or breast-bone.

The breast bone (*sternum*) is a trilateral, boat-shaped bone, concave internally, convex with a middle longitudinal crest externally, with the base of the triangle above, and the apex, which is also incurvated backwards, below. The middle longitudinal crest, which is occasionally named the keel (*carina*), is shaped something like a spherical triangle, with the broadest side above, the base before, and the apex behind; and its prominence forms large spaces on each side for the attachment of the pectoral and other muscles used in flight. In the male wild swan (*anas cygnus*), in some species of curlew, in the crane, and in the guinea-fowl, this crest forms a cavity for the reception of the windpipe. In the ostrich and cassowary, which do not fly, the sternum is void of crest, and is merely arched strongly.

The ribs.

The ribs, which rarely exceed 10 pairs, may be distinguished into sterno-vertebral and vertebral. Though the latter are generally before, they are sometimes also behind. The vertebral end terminates in two diverging processes, one of which is articulated with the vertebral body, the other with the transverse process. The sternal extremity consists of a bony process, which performs the part of the sterno-costal cartilages of the MAMMALIA by uniting the rib to the sternum. The ribs of birds, however, are further distinguished by presenting near their middle a flat long process, projecting from the rib backwards at an acute angle, and resting on the rib immediately below, so that each rib is supported not only on the vertebræ and sternum, or the vertebræ alone, but on the next rib below. These processes are obliterated in the lower ribs.

Basin or pelvis.

The coxal bones constitute one piece with the sacrum and lumbar vertebræ. The ischial portion is united with the sacrum, and the ischiatic notch is converted into a hole. The part which corresponds to the *os pubis* of the MAMMALIA is not consolidated before so as to form a symphysis, but proceeding directly backwards, terminates in a styloid process, variable in length and slenderness. The only exception to this mode of structure occurs in the ostrich, in which the pubal bones are united below. The infra-pubal or oval hole is present in the whole class notwithstanding. It is worthy of remark, however, that in young birds this and the ischial aperture are still notches, in consequence of the deficient ossification of the parts.

The direction of the *pelvis* in birds is nearly that of the spine, that is, obliquely backwards, and deviating but little from the horizontal line.

Collar-bone.

The wings or thoracic extremities are connected to the trunk by three bones, the collar-bone or clavicle, the *scapula*, and the bifurcated bone. The collar-bones, which

Comparative Anatomy.

are straight, strong, and cylindrical, are articulated by a large head with the anterior and lateral part of the sternum, in which its motion is rather limited. It forms before and laterally two short processes, one anterior-inferior and internal, articulated with the bifurcated bone; the other posterior-superior and external, uniting with the scapula, and forming a cavity, in which the head of the *humerus* is lodged.

Shoulder-blade. The *scapula* is a long bone, flattened, but narrow, and slightly incurvated, with the convex side turned towards the spine, to which it is nearly parallel in position. The head or anterior extremity is thick and extensive, oblique from before backwards, and is articulated behind with the clavicle, before with the *humerus*. The free extremity is thin, flattened, and sharp. The whole bone is not dissimilar in shape to a scimitar.

Bifurcated bone, or *Furcula*. Besides these, which BIRDS possess in common with the MAMMALIA, we find an azygous bone, situate on the mesial plane, denominated in ordinary language the *Merry thought*, and, from its shape, the fork-like or bifurcated bone. It consists of two long, rounded, converging branches, united at an acute angle, and forming a broad process, flat in the vertical direction, and by which it is articulated to the anterior extremity of the crest or carinated part of the breast-bone. To the posterior or free extremities of the divergent branches are articulated the humeral ends of the collar-bones, which are thus enabled to sustain the violent motions of the humerus during flight. The branches of the bifurcated bone are separate in the ostrich, and each is united with the clavicle and *scapula* of the same side, so that the three bones form only one, much flattened, and with a hole towards the sternal extremity. In the cassowary the bifurcated bone is reduced to a mere rudimental process at the inner margin of the head of the clavicle. From these facts it results, that the bifurcated bone is particularly useful in the energetic and continued efforts of the wings in flight, and not only serves to keep the clavicles apart, but, by lengthening the distance between the collar-bones and sternum, enables the animal to use a longer lever. It is freest, strongest, and most elastic in the birds which fly best. In birds which do not fly, and which use the wings merely to sustain the equilibrium, as the ostrich and cassowary, it is reduced to almost nothing, or it is in such a rudimental and imperfect form, that it cannot keep the collar-bones apart.

Thoracic extremities. The bones of the thoracic extremities, or those of the wings, correspond in general to those of the MAMMALIA. They consist of a single cylindrical humerus, articulated with the *scapula* and collar-bone above, two bones of the fore wing corresponding to the *ulna* and *radius*, two bones of the *carpus*, two of the *metacarpus*, consolidated by their extremities, one styloid bone as a thumb, a long finger consisting of two *phalanges*, and a short one consisting of one. The thumb supports the bastard pinions, the large finger and *metacarpus* the primaries, while the small one, which is covered by the skin, is destitute. In several of the web-footed divers, for instance the duck and penguin (*alca impennis* and *spheniscus*), these bones are flattened like thin plates.

Pelvic extremities. In the pelvic extremities the thigh-bone is provided with one trochanter only, is shorter than that of the leg, and is almost invariably straight; and is arched only in the cormorant, duck, and dobchick. In the ostrich its diameter is about four times that of the *humerus*. The *tibia* differs from that of the MAMMALIA chiefly at its lower extremity. While the *fibula* adheres to it like a slender appendage as far as the middle, the tarsal extremity terminates in two trochlear condyles, with an intermediate pulley-like groove. The *tarsus* and *metatarsus* are represented by a single bone of considerable length, and the head or tibial end of which consists of a middle prominence and two lateral depressions, and which, therefore, moves in cardinal opposition, but does not admit of extension beyond the straight line. Though variable in proportion to the length in different orders, this bone is very long in the order GRALLÆ (GRALLATORES). It terminates below in 3 pulley-shaped processes, to which are attached the bones of the 3 anterior toes, with an internal margin for that of the great toe. In the ostrich there are 2 processes only, corresponding to the two toes. In the penguin tribe, however, the *tarsus* and *metatarsus* consist of 3 bones, separate from each other in the middle, but united at the tibial and digital extremities. To the tarso-metatarsal bone of the cock, and others of the Gallinaceous tribe, is attached the spur, a conical pointed excrescence of hard horny matter.

SECT. III.—OSTEOLOGY OF THE REPTILES.

The number of vertebræ, and all the other attributes of the spinal column, vary more in this class than in all the others.

Vertebræ. In the CHELONIAD or Tortoise family there are 7 cervical, 8 dorsal, connected with the shell in an immovable piece, so as to have neither processes nor articular facettes; from 3 to 5 lumbar and sacral, consolidated in like manner; and about 20 caudal or coccygeal. (Plate XXXIV. fig. 5.)

In the SAURIAL or Lizard tribe, the number 7 predominates in the cervical, being that of the crocodile and most lizards. In several, however, there are 8, as in two of the monitor genus, the American safeguard, the lizard of Fontainebleau, the dragon, the iguana, the anolis, and the gecko and scinc; and in a few, as the Nilotic monitor, and an undetermined species of monitor, they amount to 9. In the chameleon there are only 5 cervical vertebræ. Here, however, a singular peculiarity is observed. Instead of the cervical vertebræ being, as in the MAMMALIA, distinguished by being unconnected with ribs, to those, from the third to the seventh inclusive, short ribs, unconnected with the sternum, are attached. The *atlas* and *axis*, therefore, alone are proper *cervical* vertebræ; but the general analogy is observed in the cervical ribs being exceedingly short and almost rudimental. The dorsal vary from 11, which is that of the crocodile and iguana, to 29 and 30, which are the numbers in the New Holland scinc and Nilotic monitor. In the American safeguard, *cordylus*, stellio, crested basilisk, dragon, guana, and great anolis, they are 16; in the chameleon, black safeguard, and ameiva, 17; in the tupinambis, spotted gecko, and golden scinc, 18; in the green lizard and spotted guana (*polychrus*) 19; in the Fontainebleau and gray lizard 20; 21 in the Levant scinc and undetermined monitor; and 22 in the Java and New Holland monitor.

The BATRACHOID or Ranine reptiles are void of ribs, and it is impossible therefore to distinguish the first three orders of vertebræ from each other. In general, however, there are from the nape to the *pelvis* 8 vertebræ, all provided with long transverse processes, and which are longest in the last. The *sacrum* is represented by a long flattened but pointed bone, without *coccyx*. In the Surinam toad (*rana pipa*) the last vertebra is consolidated with this bone; and the transverse processes of the second and third vertebræ are so much larger than the others, that they resemble rudimental ribs. In the Salamander family there are from the head to the sacrum 14 vertebræ, all alike in shape except the first, which receives the occipital bone, and the last, which is articulated with the sacrum. These two are distinguished by wanting rudimental ribs, which are small elongated bones, movable, and articulated with the trans-

verse processes, which are directed backwards. The articular processes are large and imbricated, the posterior resting on the anterior, so as to resist the motion of the spine backwards. The sacrum consists of one vertebra only, but the coccyx or tail is composed of 27.

In the SERPENTINE tribe the vertebræ may be said to attain the most extensive numerical developement. With the exception of the head and rudimental ribs, they constitute the whole skeleton. (Fig. 3.) From the head to the tail their shape is the same, and may be distinguished into body, articular and transverse spinous processes. In some species, for instance the *boa*, the spinous processes of the back are so much separated as to allow mutual motion to a considerable extent. In others, conversely, for instance the rattlesnake, these processes are so long and broad as to touch each other, while the oblique processes, which form their bases, are imbricated over each other. In consequence of this arrangement the motion of the spine is limited behind, but more extensive on the ventral surface. The vertebral bodies, which move easily on each other, are provided with a sharp spine directed towards the tail, which somewhat limits motion in this direction.

The first vertebra differs from those of the rest of the body in supporting short or rudimental ribs; there are therefore no cervical vertebræ and no proper neck in the serpent family. The caudal vertebræ are distinguished by not supporting ribs, and by their spines both dorsal and ventral being double, and forming two rows of tubercles. The articulation of the bodies of these vertebræ is peculiar. On the anterior part of the body is a round hemispherical tubercle, while the posterior presents a corresponding cavity, so that each vertebra forms a cup and ball joint with the following one.

The number of costal vertebræ varies from 32, which is that of the blind worm (*Anguis fragilis*), to 204 in the ringed snake (*Coluber natrix*), 244 in the snake, and 252 in the *Boa constrictor*, and which is perhaps the greatest known number. Of intermediate numbers, the *Amphisbæna* has 54, the viper (*Coluber berus*) has 139, the rattlesnake 175, and the cobra di capello 192. The caudal vertebræ vary in number from 7, which is that of the *Amphisbæna*, to 112, which is that of the *Coluber natrix*. Of intermediate numbers, the blind worm has 17, the rattlesnake 26, the boa 52, the viper 55, and the cobra 63; from which it appears that the number of the caudal is not in proportion to that of the costal vertebræ.

Cranium. Of the heads of the CHELONIADS, the most remarkable characters are, that the facial line is horizontal, and quite continuous with the cranial line; that the orbits, though complete without, are continuous behind with the temporal fossæ; that the parietal and occipital bones are compressed laterally, while the latter terminates above in a sharp spine, projecting behind. The occipito-parietal and occipito-temporal sutures are distinct. The cranial cavity is small compared with the volume of the scull.

These characters are not less remarkable in the SAURIAL or LACERTINE Reptiles. The cranium of a crocodile measuring from 13 to 14 feet is scarcely capacious enough to admit the thumb; and Cuvier estimates the area of the cranial section, which is oblong, at about $\frac{1}{20}$ of that of the whole head. In these animals, indeed, the bones of the superior and inferior jaws are so much prolonged, and occupy so large a proportion of the head, that small space is left for the proper cranial cavity, which indeed is an immediate continuation of the vertebral. In these animals, also, the anatomist can trace, much more distinctly than in the more perfect, the resemblance between the cranial bones and the vertebral. In the CHELONIADS, and SAURIAL especially, the occipital bone is very distinctly a cephalic vertebra.

Still more manifest is this arrangement in the RANINE or BATRACHOID and SERPENTINE or OPHIDIAL Reptiles. In the former, as exemplified in the frog, the occipital bone, which forms the posterior cranial vertebra, consists of four pieces, and has two articular processes. The middle cranial vertebra is represented by the parietal bones above and the posterior part of the sphenoid below, while between it and the occipital or posterior is contained the temporal as the organ of hearing. The third or anterior cranial vertebra is represented by the anterior part of the sphenoid bone below and the two narrow frontal bones above. The face, which may be regarded as the organ of the senses, is elongated anterior to the head, somewhat after the manner of the CHELONIAD family; while an approximation to the BIRDS is indicated in the articulation of the lower jaw, which is connected to the head by the intervention of a quadrilateral bone.

In the Serpentine family, the cranium of which is very similar in other respects, the most remarkable deviation is in the want of ethmoid bone. The lower jaw is connected to the cranium by an intermediate bone, corresponding to the quadrilateral, but of an oblong shape, and something like a collar-bone.

The chest of the REPTILE class varies much in the mode of formation. While true ribs are recognised in the SAURIAL family only, the BATRACHOID reptiles have a sternum without ribs, the SERPENTINE ribs without sternum, and the CHELONIAD ribs united into the dorsal shell, and a sternum expanded into the abdominal one. Chest.

In the SAURIAL family the ribs correspond in number to that of the costal vertebræ already mentioned, that is, 12 in the crocodile and iguana, two of which are not connected to the sternum, 17 in the chameleon, 18 in the tupinambis, and 27 in the monitor. The SAURIAL reptiles, however, are peculiar in having from 1 to 6 ribs attached to the cervical vertebræ, and the opposite ends of which are not connected to the *sternum*. These, which have been named cervical ribs, form a transition to the rudimental ribs of the SERPENTINE family, which are larger in the neck than elsewhere. The sternum of the crocodile consists of two parts,—an anterior or thoracic, which is osseous, supporting the two collar-bones,—and a posterior or abdominal, which is cartilaginous, and extends to the *pubis*, and furnishing to the abdominal parietes eight cylindrical cartilages. In the East India crocodile it appears that these lateral processes are converted into a single broad piece of cartilage on each side. (Fig. 4.) Ribs.

The ribs of the CHELONIAD family are represented by the dorsal shell, which consists of eight broad incurvated plates, identified behind with the dorsal vertebræ, and terminating before in the margin of the shell, and which are doubtless genuine ribs. In the ordinary land-tortoise (*Testudo Græca*) these are seen in the shape of elevated bony ridges, proceeding from the head of each rib in a transverse concave bend to the margin of the dorsal shell. On each side of these ridges the bone is depressed, and is united at its lowest point by a genuine suture with the adjoining ones. These sutures, however, are not continuous with those of the sterno-abdominal shell, but meet it in the intermediate points. (Fig. 5.) The sterno-abdominal shell consists, in like manner, of several transverse pieces consolidated into one. The ordinary number is eight on each side of the mesial plane, and a ninth azygous, generally placed in the centre of the shell. In a specimen, however, of the tabular tortoise (*Testudo tabulata*), in our possession, the number of the sterno-abdominal pieces is 11, of which 8 are in pairs, united on the mesial line from before backwards, and 3 azygous at the posterior tip of the shell. In young animals it is easy to recognise the unions of these constituent bones, which consist of sutures ex- Dorsal and sterno-abdominal shells of the Cheloniad.

Comparative Anatomy.

actly similar to those of the cranium in the MAMMALIA. So feeble is the union, that it often happens that the abdominal shell especially separates at the lines of junction, in the attempt to detach it from the dorsal.

The BATRACHOID REPTILES, though void of ribs, are provided with a *sternum*, which before is a cartilaginous process, terminating on a disc placed below the larynx, where it receives the collar-bones, and forms behind a broad plate placed below the abdomen, and giving attachment to the muscles. In the Salamander tribe, which are without *sternum*, the ribs consist of twelve pair of small rudimental processes, articulated with the vertebræ, but admitting of very limited motion.

Lastly, in the SERPENTINE family, though there is no sternum, the upper vertebræ are provided with costal processes, quite rudimental. The great number of these costal rudiments, amounting in the rattlesnake to 175, in the *cobra di capello* to 192, in the *coluber natrix* to 204, and in the *boa constrictor* to 252, and the freedom of their anterior extremities, enable the animals of this tribe, which are destitute of locomotive members, thoracic or abdominal, to employ the spinal column and the ribs as organs of progressive motion. On this point the reader will find some interesting observations by Sir Everard Home (*Phil. Trans.* 1812, p. 163). In the region of the neck, where the ribs acquire peculiar length, they are employed in erecting that region, and producing the expansive swelling peculiar to this tribe of animals. It is an important link in the same series of facts, that in the animal absurdly named the flying lizard (*draco volans*), the five posterior ribs are recurvated and elongated to form the bony skeleton of the membranous sails by which the animal supports itself in its desultory flight from tree to tree.

Thoracic extremities.

It is in the SAURIAL family that the locomotive extremities of Reptiles ought first to be studied. In these we find an elongated *scapula* without spine, and one short flat bone, constituting the clavicle, united to the sternum. In the iguana and chameleon this bone is broad and nearly quadrilateral, while in the tupinambis it is large and oval-shaped, with its greatest length from before backwards, and with two unossified points.

In the RANINE tribe, while the *scapula* consists of two articulated pieces, the upper towards the spine, each shoulder is provided with two collar-bones attached to the two extremities of the sternum, and the two anterior of which correspond to the bifurcated bone of birds. The *sternum*, collar-bone, and first part of the *scapula*, form one piece. In the salamander, in which the same consolidation is observed, the scapular portion is most distinct and directed to the spine, while of the clavicular portion the part connected to the sternum stretches below the chest, but, without uniting with that of the opposite side, the right glides over the left,—an arrangement which facilitates the dilatation of the chest during inspiration.

A nearer approach still to the bifurcated bone than is seen in the RANINE may be recognised in the CHELONIAD family. In these animals three bones are united to form the humeral cavity. The first is a flat, trilateral bone, situate below the abdominal and thoracic *viscera*, close to the abdominal shell, and which, notwithstanding its situation, is evidently the *scapula*. The second is a bone about the same length, flat, and like the feather of an oar at one extremity, which is free, round in the middle, and flattened in the opposite direction at the other end, which is firmly united at a right angle to a long slender cylindrical bone. At the angle of union of these two bones is part of the glenoid cavity, which is complete in the small end of the scapula. The first of the two bones is the collar-bone proper; the second is the lateral branch of the bone, which forms the bifurcated, and which is occasionally united with its fellow. (Plate XXXIV. fig. 5.) The abdominal shell we have already stated to represent the sternum or breast-bone.

The *humerus* in the SAURIAL and CHELONIAD family is arched and incurvated in a serpentine direction. It is articulated with a *radius* and *ulna*, which are succeeded by three rows of carpal bones, one row of four metacarpal bones and digital phalanges, varying in number in different *genera*. In the skeleton of a fossil animal belonging to the SAURIAL tribe, originally delineated by Collini, and afterwards by Cuvier, and named by him the *Pterodactyle* or Wingtoe (*Pterodactylus*, *OSSEMENS FOSSILES*, tome v.), the metacarpal bone and *phalanges* of the *index* are prolonged to about twenty times the ordinary length, for the purpose, apparently, of giving attachment to the membranous web by which the animal occasionally elevated itself into the atmosphere. This animal, which, like the dragon (*draco volans*) of modern times, must have combined the contradictory characters of a flying reptile, may be regarded as forming the link between the REPTILES and BIRDS, as the *Ichthyosaurus* does between REPTILES and FISHES.

Fossil skeleton of winged reptile.

Pelvis.

In the *pelvis* of the CHELONIAD family it is remarkable that the pubal and iliac bones appear to change places. Thus the *ilium* on each side is a narrow bone proceeding backwards to the sacral part of the spine, which is received between its posterior aperture; while the *pubis* appears in the shape of a broad, trilateral, flat bone, uniting before with its fellow on the mesial plane, behind with the *ilium*, and below with a flat, thin, quadrilateral bone, corresponding to the *ischium*, with which it forms the oval aperture. The inner of these three bones presents, as usual, the cotyloid cavity. It is further to be observed, that the two iliac bones, and consequently the whole *pelvis*, are movable on the vertebral column. (Plate XXXIV. fig. 5.)

Pelvic extremities.

In the SAURIAL Reptiles the pelvic bones are arranged and shaped nearly as in the CHELONIAD. In the RANINE the iliac bones are much elongated, and the pubal and ischial are consolidated into one piece, the symphysis of which forms a rounded crest.

The *femur* is short, thick, and incurvated sinuously, with the convexity before towards the tibial end, and the concavity towards the pelvic. Trochanters, though present in the CHELONIAD, are wanting in the SAURIAL and RANINE Reptiles. In the leg we find both *tibia* and *fibula* distinct, and of nearly equal size, in the CHELONIAD and SAURIAL family, but conjoined in the RANINE family. The *tarsus* consists of five bones, and sustains four or five metatarsal ones, on which are supported three rows of phalanges. The metatarsal bones, which vary in length, are longest in the crocodile and others of the LACERTINE tribe. In the RANINE, again, the *astragalus* and *calcaneum* are the bones of greatest proportional length.

The anatomical characters now enumerated are proper to the skeletons of Reptiles at present existing on the surface of the earth or in its waters; and in these we find a gradual transition from the SAURIAL and CHELONIAD, by means of the SERPENTINE, to the finny inhabitants of the ocean. Even the BATRACHOID Reptiles, in the early period of their existence while tadpoles, we shall have occasion to see, approach to the FISHES; and in one singular genus, if not two, the *Proteus anguinus* and *Siren Lacertina*, the characters of the Reptile are combined with those of the Fish, in having at once lungs or internal respiratory cells, and gills or external ciliated branchiæ. The transition thus indicated is still more strongly demonstrated in the osteological characters of two *Genera* of animals now extinct, so far as is yet known,—the *Ichthyosaurus* and the *Plesiosaurus*.

Comparative Anatomy.

Osteological peculiarities of the Ichthyosaurus

From the specimens of the *Ichthyosaurus* hitherto discovered, it appears that the number of vertebræ varies from 80 to 90 or more; in one entire specimen they amounted to 104 (Conybeare and De la Beche); that they are flattened, with the transverse diameter greater than the longitudinal, and the two articulating surfaces of the bodies calycoid or cup-shaped as in Fishes. Though the annular part is distinct from the body, it is united to its sides. The spinous processes, which are long and prominent, form a continuous ridge above the spine, and are connected to each other by a process from the front of the one spine, which is inserted into a pit in the back of the other. Instead of proper transverse process, a certain number of the vertebræ are provided with two tubercles on each side of the body, of which the superior, convex, is articulated to the tubercle of the rib, while the other, which is concave, receives the head. In the inferior part of the vertebral column, these two tubercles, after approximating, are eventually identified into one.

The ribs, which are numerous, and extend from the *occiput* to the *pelvis*, are slender and trilateral in shape, bifurcated above, and attached to the vertebræ by a head and tubercle. In the perfect specimen of Mr de la Beche they amount to 31, and of these 17 appear to be cervical or anterior false ribs, with single tubercles; thus affording another mark of resemblance to the Saurial family in osteological characters.

The bones of the head, distinguished by the extraordinary size of the orbit, are similar to those of the Saurial Reptiles. The *sternum*, collar-bone, and scapula, though also similar to those of this family, bear a much closer resemblance to the figure of these parts in the *Echidna* and *Ornithorhyncus*. The *humerus* is short, thick, and sinuated; the bones of the fore arm flat, and probably constituting part of the fore or thoracic fin. The *Carpus* consists of three rows, the first containing three bones, the other two, four each. These are followed by five or six rows of flattened, irregularly cuboidal bones, gradually diminishing in size and number to the tips, and which represent at once the *metacarpus* and *phalanges* of the fore paw, used apparently chiefly as a fin or paddle. The pelvic extremities appear to have been less strong and perfectly constructed than the thoracic. The *femur* is smaller and shorter than the *humerus;* the *tibia* and *fibula* are flattened like the *ulna* and *radius;* the *tarsus* consists of two rows only, the first containing three, and the second five bones; and this in like manner terminates in five ranges of flattened bones, gradually diminishing in size, and which represent the *metatarsus* and metatarsal phalanges of the hind paw or paddle.

and Plesiosaurus.

From the specimens hitherto discovered of the *Plesiosaurus*, it appears that the total number of vertebræ amounts to 90, of which 35 appear to be cervical, while the other 55 are dorsal and caudal, the regions of which are proportionally short. The head of this animal also is small and compressed, nor has it the large orbit of the *Ichthyosaurus*. Each rib consists of a vertebral and sternal portion, united at an obtuse angle, the former articulated by a single head to the transverse process, and the latter connected with its fellow by a transverse slip, so that the lower or abdominal ribs appear to have surrounded the abdomen with a complete cincture. The anterior part of the chest is occupied by two trilateral bones uniting in the middle, which, from their connection with the scapula, are believed to be the coracoid bones; and above these is a transverse piece, with a middle notch and lateral sinuated elevations, which is regarded as the *sternum;* while the *scapula* extends on each side like a buttress between the two. It is not improbable, nevertheless, that the middle portions named coracoid bones are the sternum, and the transverse bone the clavicles; and it is worthy of remark, that not only this bone, but the middle piece, closely resembles in figure and disposition those of the *Echidna* and *Ornithorhyncus*. The *pelvis* consists of three bones, a vertebral or superior, corresponding to the *ilium*, narrow and slightly incurvated; an anterior, ascending forwards, and broad, separating the *pubis;* and a posterior, short, forming the *ischium*. The humerus and femur are longer than in the *Ichthyosaurus*. There is a very short *radius* and *ulna*, and *tibia* and *fibula*, articulated with five carpal and tarsal bones; and the rest of both paddles consists of successive rows of flattened but long bones, contracted in the middle, and expanded at the extremities, representing the metacarpal and metatarsal digital phalanges. (Home, *Phil. Trans.* 1816, 1818, 1819, 1820; De la Beche and Conybeare, *Geological Transactions*, vol. v. p. 559; and Cuvier, *Ossemens Fossiles*, vol. v. part ii.)

SECT. IV.—OSTEOLOGY OF THE FISHES.

The Serpentine or Ophiad Reptiles present in their osteological characters an approximative transition to those of Fishes. While in the former order the skeleton is reduced to the spinal column, ribs, and head, in the latter class the spine and head only are left; and in some tribes the transition is still more distinctly marked by the presence of ribs.

Vertebræ.

The vertebra of a fish is distinguished from that of any other animal by the shape of its body. The cephalic and caudal, or anterior and posterior surfaces, are hollow cup-like cones, so that the union of each two vertebræ forms a double conical cavity, united by the base, containing a substance composed of concentric fibro-cartilaginous layers, with intermediate albuminous or gelatinous matter. By this cartilage the vertebral bodies are united; and on this the motions of the spine are effected. This motion, however, is chiefly lateral; for the spinous processes are so long, and the articulation so complex, that antero-posterior inflection or extension is nearly impracticable.

In the cartilaginous fishes, for instance the shark, sturgeon, and lamprey, the vertebral bodies form simple tubes, which, from the extreme elasticity of the constituent cartilage, propel the contained fluid to a considerable distance. Thus Sir E. Home saw the fluid projected to the height of four feet from the intervertebral cavities of the shark. (*Phil. Trans.* 1809.) In this order, also, the spine is infinitely more flexible, and its resilient power, when bent by the muscles, is almost incredible. On each side, also, the vertebræ are excavated, to form a canal for lodging the large blood-vessels.

The vertebræ of fishes are numerous, and not easily distinguished into classes. They may, however, be distinguished into two, according as the spinous process is above only, or above and below at once. Those with the dorsal spine only are denominated *dorsal or abdominal vertebræ*, and have commonly at the sides transverse processes for the attachment of the ribs. Those with the dorsal and ventral spines are distinguished as the *caudal vertebræ*. The last caudal vertebra is generally trilateral, flattened in the vertical direction; and its tip is marked with articular pits, which indicate the attachment of the small elongated bones which sustain the caudal fins.

The number of vertebræ varies. In the *uranoscopus* or star-gazer there are only 25, in the *balista* 17, and in the four-spined trunk-fish (*ostracion*) only 13; while in the sturgeon the number is 84, in the eel 115, and in the shark 207.

Though Fishes have no chest, and require none, since their respiratory organs are gills, all of them are not void of ribs The ray, shark, *syngnathus*, *tetraodon*, *diodon*, *cy-*

Comparative Anatomy.

clupterus, *fistularia*, &c. have indeed no vestige of rib. But in the sturgeon, *balista*, eel, *uranoscopus*, *pleuronectes*, sea-wolf, and dory, they are in the shape of short rudimental processes; in the *trigla* and *loricaria* their sides are horizontal; in the perch, carp, pike, and *chetodon*, they encompass nearly the whole upper region of the abdominal cavity; and, lastly, in the silver-fish (*zeus vomer*), the herring, rhomboidal salmon, &c. they are united to a sternum. In the little animal named sea-horse (*syngnathus hippocampus*), several series of osseous tubercles of the skin, surrounding the body like belts, are supposed to represent false ribs. The sternum is limited to a small number of FISHES. Besides those already mentioned, in the dory there is a series of minute flat bones disseminated along the lower edge of the belly, which is supposed to represent a rudimental sternum.

In size and number the ribs vary, though in the *silurus*, carp, and *chetodon* they are of largest proportional size; in the herring they are as fine as hairs.

The head. Cranium.

The head in the finny tribes is more an object of zoological than anatomical description. The chief points to be remarked are, that the cranium forms but a small part of the head; that the orbits are separated by a *septum*, sometimes membranous, occasionally, as in the wolf-fish, bony; and that there is on each side a large movable bone, corresponding to the quadrilateral of BIRDS, not square, however, but oblong, which supports not only the lower jaw and palatine arches, but the gill-cover. In the cartilaginous fishes the sutures are early obliterated, and the cranium consists of an inseparable mass of cartilage. In the bony fishes the cranium is separable into numerous pieces, and in the perch they amount to 80. In the cranium of fishes the anatomist recognises more distinctly than in the superior orders the formation according to the vertebral type. Small in proportion to the whole head, the cranium appears like a direct continuation of the vertebral column. In the osseous division of the class especially, the cranium may be distinguished into the occipital or posterior vertebra, the spheno-parietal or middle, and the frontal or facial vertebra. The cavity thus formed is very small; yet small as it is, it is not exactly filled by the brain, between which and the bones there is interposed a pellucid fluid, contained in fine cellular tissue. The cranium of the osseous fishes also is widest between the ears, because the organ of hearing is contained within its cavity with the brain. In the cartilaginous it is quite different.

Locomotive members or fins.

Though FISHES are destitute of extremities similar to those possessed by the other three classes of the VERTEBRATA, they are not, however, without locomotive members. The thoracic extremities are represented by the pectoral fins, and the pelvic by the ventral. In short, it may be said that the bones of the thoracic and abdominal extremities are converted into osseous rays in the finny tribes.

Pectoral fins.

In the Ray *genus*, in which the wing-like disposition of the pectoral fins gives the body a rhomboidal shape, they consist of numerous radiating cartilaginous lines, all attached to a cartilage parallel to the spine, divisible into two or three others, and articulated above to another adherent to the spine. Below there is a strong transverse bar common to the cartilages of both fins, and separating at once the sternum and clavicle. This transverse bar is also seen in the shark tribe; but their pectoral fins, which are much smaller, are not articulated with the spine.

In the osseous fishes, and in many others usually referred to the cartilaginous division, *e. g.* the *balista*, the pectoral fins are fixed to an osseous belt, which surrounds the body behind the gills, and which supports the posterior margin of their aperture. This belt consists of a single bone on each side, articulated to the posterior-superior angle of the cranium, and uniting below the breast with that of the opposite side. This bone, which may be regarded as a *scapula*, varies in shape and the angle which it forms with its fellow in different species. In fishes flattened vertically, the angle of union is acute; in those which are depressed, the angle is so obtuse as to form nearly a straight line. In many fishes, especially those of the order THORACICI, *e. g. pleuronectes*, *cottus*, *zeus*, *chetodon*, perch, &c., in the small unicorn (*balista*), and others, the superior part forms a large spine, which descends immediately behind the fin, and to which the *adductor* muscles are attached. This spine, which is movable, has been improperly named a *clavicle*.

The rays by which the membrane is supported are not directly articulated to this belt, but are connected by a row of minute flat bones, which may be compared to the *carpus* in the other three classes. When the first ray of the pectoral fin, however, is thorny, as in the harness-fish (*loricaria*), and some species of *silurus*, it is articulated directly with an osseous belt; and it is remarkable that some fishes, as the *silurus* and stickle-back, have the power of retaining this spinous ray erected against the body as a means of defence. This is effected by a cylindrical tubercle, on which the spinous ray is articulated by a hollow, bounded before and behind by an elevated process. When the spine is erected, the anterior process, entering a hole in the cylindrical tubercle, is locked in it by the spine revolving slightly on its axis, so that it cannot be inflected unless by the spine revolving in the opposite direction.

Pterygoid pectoral fins.

The pectoral fins are so long that they answer the purpose of wings in several species of *trigla*, the *trigla hirundo*, the flying gurnard (*trigla volitans*), the springing gurnard (*trigla evolans*,) in the *scorpæna volitans*, the tropical flying fish (*exocœtus volitans*), and some others. Their situation also is liable to vary. In the *exocœtus* they are near the gills, but in the *blennius* and others they are remote. Lastly, they are totally wanting in a small number only, as the lamprey (*petromyzon*), the hag-fish (*myxine*, Lin.; *gastrobranchus*), the *murœna*, the eel *genus*, the *sphagobranchus*, &c.

Abdominal or ventral fins.

The abdominal or ventral fins, which correspond to the pelvic extremities of the other classes, are so denominated because in the majority of fishes they are situate below the belly, and nearer the anal outlet than the pectoral. By this circumstance a numerous order are distinguished by the name of Abdominal Fishes (ABDOMINALES).

In a small number of fishes, comprehending the *gadus*, *blennius*, *kurtus*, *callionymus*, *trachinus*, and *uranoscopus*, the ventral fins are placed under the throat, below the aperture of the gills, and before the pectoral fins. This order is therefore distinguished by the name of JUGULARES.

In the most numerous order of all, the ventral fins are situate behind and below the pectoral fins. These have therefore been denominated Thoracic Fishes (THORACICI).

The ventral fins consist of two parts—one formed of rays covered by a double membrane, apparent externally, and constituting the proper ventral fin; the other internal, representing the coxal bones of the *pelvis*, always supporting the pinnal rays, and often articulated with the bones of the trunk. It is never articulated, however, with the spine, nor does it form an osseous belt round the abdomen. The bones of which it consists are generally flattened, varying in shape, and in mutual contact by the internal margin. In the shark and ray *genera* only is there a single transverse bone, nearly cylindrical, to the extre-

Comparative Anatomy.

Ventral fins.

mities of which the fins are attached. The direction of the pelvic plane to the walls of the abdomen varies according to the shape of the body of the fish. In the flat fishes they are directed obliquely, and their inner margin forms the keel of the belly. In fishes with a broad or cylindrical belly they form a plane more or less horizontal.

In the Jugular and Thoracic Fishes, the pelvic bones are always articulated with the base of the belt which sustains the pectoral fins; and they vary much in shape and situation.

In the *trachinus*, *uranoscopus*, *cottus*, *sciæna*, *chetodon*, and perch, these two bones are united by their inner margin. In the cuckoo-gurnard, in which they are united by the posterior tip only of their internal margin, they are broad, flat, and oval. In the sole and flounder *genus* (*pleuronectes*), in which the fins are attached to their anterior tip, they are united in a quadrangular pyramid, the apex of which is directed backwards and upwards, and the base forwards. In some of the stickle-backs these bones are altogether separate, and being long, receive in their middle a movable spine, which supplies the place of the ventral fin. In the dory (*zeus faber*, L.) they are flat and triangular, in mutual contact by their whole surface. In the silver-fish (*zeus vomer*) they are small and cylindrical.

In the whole of the Abdominal order, on the contrary, the pelvic bones are equally unconnected with the bones of the shoulder and with the osseous belt of the pectoral fins, and are confined to the middle-inferior part of the belly, not far from the *anus*. In general these two bones are separate from each other, and are retained in their situation by ligaments. In the carp, in which they are elongated, they touch only by their posterior third. In the herring, in which they are small and approximated, they are continuous with the minute bones of the sternum. In the pike they are broad and trilateral, approximated by their anterior tips, separate behind where the fin is attached. In the *silurus*, in which they are united, they form a round and often spinous shield before, while the fins are attached to the exterior-posterior margin. Lastly, in the cuirassier or harness-fish (*loricaria*), the pelvic bones are united in one piece, the posterior notch of which forms the anal aperture, while the fins are attached to its external margin.

The proper fin consists of a certain number of osseous rays, simple or bifid, supported by one or two rows of minute bones placed between them and the pelvic bones. On these small bones the constituent rays move, diverging or converging like the rods of a fan, while the whole fin may be inflected or extended by the minute bones moving on the pelvic, so as to adduct or abduct the fin.

In the cartilaginous fishes the structure is different. To the tip of each pelvic bone are articulated two principal cartilages, one external, forming a kind of toe with seven or eight joints; the other internal, supporting all the other rays of the fin, which often exceed thirty in number.

Analogy or unity of principle in organisation.

If we suppose these bones, like the minute ones of the pectoral fin, to represent the *tarsus* of the other three classes, it must follow that, in the locomotive extremities, the *humerus*, with the *ulna* and *radius*, and the *femur*, with the *tibia* and *fibula*, are obliterated. It is not unimportant to observe, that the general structure of the Vertebrata tends through various transitions to this termination. In the Amphibia the long bones of the extremities are shortened by removing the *diaphysis*, and leaving their articulating ends only. In the Cetacea the pelvic extremities are removed altogether. In the Cheloniad and Saurial Reptiles the same long bones of the extremities are much abridged; and in the Ichthyoid Reptiles, now extinct, but sharing by their structure a form of animal existence partaking of the reptile and fish at once, and perhaps intermediate between the two, this abbreviation is carried perhaps to its greatest possible degree, in leaving the articular ends only of the four locomotive extremities. Lastly, this reduction is merely preparatory to that exhibited in the whole class of Fishes, in which the three longitudinal bones so conspicuous in the higher classes of animals are completely obliterated, and those representing the hand or forepaw and foot are articulated directly to the shoulder and pelvic bones.

Besides the bones already mentioned as constituting the skeleton, there are observed in the osseous fishes minute bones, generally fork-like in shape, disseminated through all the muscular parts of the body. The purpose of these bones, which, as being totally insulated from the other parts of the skeleton, are denominated *ossicula musculorum*, is chiefly to afford points of support; and they are probably to be regarded as rudimental representatives of osseous parts, more completely developed in the higher animals.

Violation of the law of symmetry.

It is further a curious circumstance, that the skeleton, which is so symmetrical in all the other classes and orders, begins to exhibit a deviation from this first in the skeleton of the finny tribes. In the Sole *genus* (*Pleuronectes*) this deviation is very conspicuous. Both eyes are placed on the same side of the mesial plane; and the side on which the eyes are placed is broader than the opposite one. The former is bounded by a convex margin, the latter by a concave one. The orbit towards the former is large, the other small and imperfect. Conversely, it is to be observed, that in the latter the maxillary and intermaxillary bones are larger than in the former. The sides of the inferior jaw are less discordant; and though in the Sole and Plaice those of the eyeless side are more straight and elongated than those of the other, in the Turbot (*Pleuronectes maximus*) they are nearly symmetrical.

CHAP. II.—COMPARATIVE MYOLOGY.

Though this is the proper place to consider the peculiarities of the muscular system of animals, the limits assigned to this sketch will not allow us to enter into details. We shall merely, therefore, take a cursory view of those points in which the myology of the lower animals differs from that of the human subject.

In general, in the lower animals, especially the Mammalia, Birds, and Reptiles, the muscles correspond in situation to those of the human subject; and whatever modifications they undergo consist in changes of figure, and in some few instances in changes in attachment. The former kind of changes may be in all cases pretty accurately estimated by the osteological characters of the class, order, or genus; for when the position, shape, or direction of a bone is altered, in the same proportion nearly are the attached muscles altered in their attributes.

Deficiency in number.

Though in the lower animals, however, the zootomist traces muscles in general quite analogous to those of the human subject, in several instances this analogy ceases to be observed. In general the muscles of the lower animals are less numerous than those of the human subject; and this deficiency in number, though not much observed in the Quadrumana, is very remarkable in all the inferior orders of the Mammalia, and still more in the Birds and Reptiles. In general, also, these variations are most conspicuous in the locomotive extremities. Thus the small pectoral muscle, which is present in the Quadrumana, is wanting in the Carnivora and the whole of the Ungulated Animals and the Reptiles. The short *supinator* is present in the Canine and Feline *genera*, but the long is wanting; and both are absent in the Chiroptera, Rodentia, Pachydermata, Ruminantia, and

Comparative Anatomy.

Solidungula, and in the whole class of Birds. Both pronators (*teres* and *quadratus*) are present in the Quadrumana and Carnivora, but wanting in the Chiroptera, Ruminants, and Solidungula. The Rabbit, and perhaps the Rodentia generally, have the *pronator teres;* but as the radius is not very movable, its influence is trifling.

Myological peculiarities of the mole.

In the mole the *rhomboideus* is inserted into the cervical ligament, which is ossified; and it therefore elevates the head and neck on the *scapula* with singular force. This is effected still more remarkably by the occipital part of the *rhomboideus*, the fibres of which being parallel to the spine, pass below the proper *rhomboideus* to be attached to the transverse ligament and the middle of the *cranium*. The strong, thick, quadrangular collar-bone has two muscles, a *supraclavius* and a *subclavius*. The large pectoral is very thick, and nearly as large as in birds.

The common extensor of the fingers or fore toes is the only muscle which is common to man and all the quadrupeds. Of the proper extensors the horse has two on the side of the common extensor, but acting as an extensor of the fore pastern; another between the common extensor and the extensor of the pastern, and which seems merely an appendage to the former. The proper extensor of the index is wanting in the Rodentia, Ruminants, and Solidungula; and while the two latter orders are destitute of the long and short extensors of the thumb, and the feline, canine, ursine, and leporine *genera* have the former, they are destitute of the latter. Lastly, the lower animals are wholly destitute of the short muscles of the hand, which in man produce flection, abduction, adduction, and opposition. In the Chiroptera only is there one extensor, and flexors of the fore toes.

Among the muscles of the pelvic extremities the *glutæus maximus*, or large muscle of the buttock in man, diminishes much in the Quadrumana; and in the other orders is reduced to a very small size. The buttock in the Mammalia generally consists chiefly of the *glutæus medius* and *minimus;* and while the *glutæus maximus* is in the horse in a great part aponeurotic, the *g. medius* is so large as to produce those forcible and sudden extensions of the hind leg which constitute the kick.

In the leg the *sartorius* of the horse, the animal in which the muscles have been most studied, is large, and is distinguished by the name of the long *adductor*, in opposition to the *gracilis*, which constitutes the short *adductor*. The muscle representing the *biceps* of man is in all quadrupeds a *uniceps*, and the single head is attached to the ischium only. In the horse and dog it has been denominated the *vastus longus*.

The *gastrocnemius externus et internus* (*gemellus*), which constitute the calf of the human subject, diminish considerably in the lower animals; and the *solæus*, which is placed below them, also becomes small, and is particularly slender in the Ruminants and Solidungula.

Muscles wanting in birds.

The following muscles are wanting in the whole class of Birds. The diaphragm, the *recti abdominis*, and the *pyramidales;* the muscles of the dorsal part of the spine, the *splenius*, the *brachialis externus*, or third head of the *triceps;* the supinators of the fore arm or wing, as already mentioned, all those corresponding to the short muscles of the hand and fingers; the *quadratus lumborum*, the *psoas parvus*, the *psoas magnus*, *iliacus internus*, *obturator externus*, and the *extensor longus pollicis pedis*.

Two muscles, which occupy the situation of the pronators, act as flexors, showing the connection between the actions of inflection and pronation, and the occasional substitution of the latter for the former.

In this class, also, the *glutæus maximus* is of a pyramidal shape, while the true *pyriformis* is wanting. The *glutæus minimus*, which is attached to the anterior edge of the iliac bones, is the *iliacus*. In place of the *pectineus* there is a slender muscle, which extends to the knee, over which its tendon passes, and gliding behind the leg, its tendon is bifurcated, one slip going back to be inserted into the posterior part of the metatarsus, the other to be united to the perforated flexor of the first and last toe. This muscle, which is named the *accessory femoral flexor*, is the one by which birds are enabled to clasp a perch during sleep.

Muscles used in flying.

In Birds the great pectoral is a remarkable muscle in point of size. It consists indeed of three muscles, the large pectoral, the middle, and the small, which occupy the sides of the vertical crest of the sternum, and constitute what is named the breast of the animal; and which are chiefly employed in the energetic motion of the wings in flying. These muscles are sometimes so large that they weigh more than all the other muscles of the animal together. In birds which fly much they are dark coloured and firm; in those which fly little, as the domestic poultry, they are white coloured, and in general soft. The same distinction is observed in the muscles of the two extremities. In birds much on the wing these muscles are dark coloured and firm, while those of the legs are comparatively lighter and more tender; and, conversely, in birds little on the wing and mostly on the legs, as the domestic poultry and many of the *Grallæ*, the waders, swimmers, &c. the muscles of the wings are light coloured and tender, while those of the legs are dark coloured, firm, and strong.

Mechanism of perching.

The flexor muscles of the leg and toes of Birds merit notice. They consist of muscles corresponding to the long flexors, which are divided into three masses. The first consists of five portions, three of which may be regarded as constituting a single *common perforated flexor*. It rises by two bellies, one attached to the external condyle of the *femur*, forming a perforated tendon, which receives one of those of the muscle corresponding to the *peronæus;* the other to the posterior surface of the femur, forming the tendons of the index and small toe. This muscle is further connected by intermediate fibres with the accessory femoral flexor,—a muscle placed on the internal surface of the thigh, and sending its tendon over the knee; and as the tendons are inserted into the unguinal phalanges, when the accessory femoral bends the thigh the flexors of the toes inflect them also, and retain them in the inflected position. By means of this arrangement birds are enabled to clasp a perch or other small body when roosting, without continued muscular effort, and thereby to sleep on the perch. This mode of explanation, which was originally given by Borelli, has been controverted by Vicq d'Azyr; but apparently not on good grounds.

Among the class of Reptiles, while the muscles of the Ophidial family are confined to those of the vertebræ and rudimental ribs, in the Cheloniad these are obliterated, and the muscles of the neck, head, and tail, and those of the locomotive extremities alone, are left. In the other two classes of reptiles the muscles are in general analogous to those of the Mammalia.

Cutaneous muscle.

There are not many instances of muscles which, though unknown in man, are found in the lower animals. Of these the most remarkable are the cutaneous muscle (*panniculus carnosus*), and the suspensory of the eye. The former was absurdly maintained to exist in the human subject, especially by Nicolaus Massa; but it is manifest that the assertion was derived from the dissection of the lower animals only. It was not long after demonstrated by Charles Etienne, that no fleshy pannicle or cutaneous muscle exists, such as is found in the lower animals; and

that the only cutaneous muscles in man are the *latissimus colli*, the *epicranius* or scalp-muscle, and those which are attached to the face, and which by their motion give expression to the countenance. The cutaneous muscle even is not found in the QUADRUMANA, nor does it exist in the pig. In various other animals, however, it is found in different degrees of distinctness. It is very well marked in the hedgehog and porcupine;—by its means they have the power of erecting their spines, and rolling themselves up;—and in the armadillo and the ant-eater tribe. In the mole, also, we have seen it pretty well marked.

Suspensory muscle of the eye proper to certain animals.

It is an interesting fact, that Galen originally observed that the lower animals possess a seventh muscle of the eye, or one more than man. The suspensory or infundibular muscle (*musculus choanoides*), as it has been named, from its shape, especially in the Ruminants and SOLIDUNGULA, has the *apex* fixed to the margin of the optic hole, and its base inserted a little behind the four straight muscles. In the ZOOPHAGA and CETACEA it consists of four parts, so that these orders appear to be provided with 8 straight muscles. In the rhinoceros it consists of two portions.

Tail,

There is yet another part, the muscles of which can scarcely be said to exist in the human subject, but which attain a very great degree of developement in the lower animals. The *coccyx* of the human subject is expanded in the lower animals into a highly flexible prolongation denominated the tail (*cauda*), variable in length, but always consisting of separate vertebræ, articulated and movable on each other. While the *coccyx* of the human subject possesses two muscles only, the *ischio-coccygeus* and *sacro-coccygeus*, which are so insignificant in size that they scarcely serve to move the part, the caudal vertebræ of the lower animals are moved by muscles greatly larger, more numerous, and more powerful.

The tail is to animals a much more useful and powerful organ than the coccyx to man. It is a member which peculiarly belongs to them; and though in ordinary circumstances pendulous, it is made to assume a variety of motions of which no other organ is susceptible, and to perform duties which would be otherwise impracticable. With many, as the long-tailed monkeys, the sloths, the ant-eater, and the squirrel tribes, it is indispensable as an organ of prehension. The majority of animals, as the Ruminants, SOLIDUNGULA, &c. use it as a whip or lash to drive away insects. The lion, tiger, and others of the feline tribe, lash their sides with it when enraged. The Cetaceous swimmers employ it as a rudder and oar in the waters. The beaver uses it as a trowel, to enable him to construct his clay-built dwelling. An organ employed so variously must consist of a muscular apparatus rather complex.

and caudal muscles.

The different motions of which the tail of the MAMMALIA is susceptible may be referred to three heads,—one by which it is extended or elevated, another by which it is inflected or depressed, and a third by which it is made to beat the sides. The combination or succession of these motions gives rise to secondary ones more complex in character. It may be twisted on its axis, or turned in a spiral direction. These motions are effected by three classes of muscles.

1*st*, The muscles which raise the tail are situate above; they are *musculi sacro-coccygæi superiores*. Commencing at the base of the articular processes of the 3 or 4 last lumbar vertebræ, or those of the sacrum and the caudal vertebræ, by fleshy slips, they are connected to tendons, which are inserted into the base of the first of the caudal vertebræ, which are void of articular processes. The second tendon goes to the next following vertebra, and so on to the 13th, each contained in a ligamentous groove, which forms an investment. The muscles of both sides acting together, elevate or incurvate the tail upwards.

The *interspinalis* and *spinalis obliquus* or lumbo-sacro-coccygeal are the continuations of the *interspinales dorsi et lumborum*. The spinous processes, however, becoming indistinct, or being represented by two tubercles, the attachments vary.

2*d*, The muscles which depress or inflect the tail downwards take their origin within the pelvis, and are prolonged to various extents along the inferior surface of the tail. Of these there are four pairs, the *ileo-coccygeal* of Vicq d'Azyr, the inferior *sacro-coccygeal*, the *inter-coccygeal* muscles, and the *pubo-coccygeal* of the same author. The insertions of these muscles vary in different genera, according to the number of vertebræ of which the tail consists. The pubo-coccygeal is wanting in the raccoon, but it is distinct in the dog and opossum. The effect of the ileo-coccygeal and it, is to depress the tail and apply it forcibly to the *anus*.

3*d*, There are only two muscles which carry the tail to the sides of the animal—the *ischio-coccygæus externus*, and the *intertransversalis* of Vicq d'Azyr; the former proceeding from the pelvic surface of the *ischium* below and behind the *acetabulum*, to the transverse processes of the caudal vertebræ, the second extending in a continued band between all the transverse processes.

The tail, therefore, in the MAMMALIA, consists of a series of successively decreasing vertebræ, moved by eight pairs of muscles.

In FISHES it is not easy to trace any analogy between the muscles and those of the other classes. Though the spine, head and fins, have appropriate muscular bundles, the natural or fascial distinctions are less evident than in the other three classes. It is important, however, to remark, that while the muscles which move the spinal column are placed in these classes, partly before, and chiefly behind the vertebræ, those of FISHES are placed on each side. Hence the lateral motion of the spine, which is inconsiderable in MAMMIFEROUS animals, BIRDS, and REPTILES, becomes very conspicuous in the finny tribes, especially in the motion of swimming, while the antero-posterior inflection or extension is altogether insignificant.

It is almost superfluous to remark, that, in the greater part of the finny tribes, the muscles are white or pale coloured. In a few only, for instance the salmon, trout, gwiniad (*coregonus*), herring (*clupea harengus*), carp (*cyprinus*), and some others, are the muscular fibres of a pale flesh red. The circumstances on which these differences depend are not known; but it is supposed that in the latter sorts the proportion of oleo-albuminous matter is more abundant than in the former. The proportion of albumen, however, in the muscles of fish, seems in general to be small. They abound in gelatine and isinglass; and in some of the cartilaginous fishes especially, the greater part of the muscles seem to consist chiefly of gelatine in various degrees of consistence. This is particularly the case with the lamprey, the hag-fish (*myxine glutinosa*), and even with the sturgeon. The sterlet especially (*acipenser Ruthenus*), a small species of sturgeon found in the rivers of Russia, both European and Asiatic, abounds in gelatine; and the presence of this principle enables the inhabitants to use it in the preparation of a species of soup, the sterlet, which is esteemed a great delicacy. In some of the *genus Pleuronectes* this principle is also very abundant. Thus the Plaice (*Pleuronectes Platessa*), sole (*P. Solea*), and especially the turbot (*P. Maximus*), contain a considerable proportion of gelatine. On the proportion of this principle depends the quality of fish used

Comparative Anatomy.

as an article of food in nourishing without exciting. All fishes which abound in gelatine uncombined with oleo-albuminous matter may be safely used as articles of food; while those in which the latter ingredients predominate are invariably eaten with the risk of disordering the stomach and producing indigestion.

CHAP III.—COMPARATIVE ÆSTHIOLOGY, OR THE COMPARATIVE ANATOMY OF THE ORGANS OF SENSATION.

SECT. I.—THE ORGAN OF SMELL.

The organ of smell consists of the nasal cavities, those of the ethmoidal and turbinated bones, and the frontal, sphenoidal, and superior maxillary sinuses, all of which communicate with the nasal. The whole of these parts are invested by fine periosteum, lined by mucous membrane. The ethmoid bone is the essential organ of smell; and the others appear simply to multiply the extent of the membrane.

The ethmoid bone consists of a perforated plate, with a middle vertical one attached at right angles to it, and lateral portions composed of thin bony plates convoluted with various degrees of complexity and minuteness in different orders and genera of animals. These convoluted plates form what are denominated the ethmoidal cells. They may be represented as numerous tortuous canals, proceeding from the perforated plate forwards and outwards, approximating mutually, and forming numerous communicating cavities. Such nearly is the structure of these plates in the EDENTATA, RUMINANTIA, SOLIDUNGULA, PACHYDERMATA, and CARNIVORA, the last of which have more complicated cells than the first. In the dog they are numerous and extensive. In the RODENTIA, for instance the porcupine, they are few—not above 3 or 4 on each side.

Ethmoid cells.

In BIRDS the internal side of each nostril is occupied by three orders of plates; the inferior turbinated or spongy bone; the middle, consisting of one plate convoluted on itself two turns and a half; and the upper, shaped like a bell, adhering to the frontal and lacrymal bones. These form three tortuous passages, varying in size and tortuosity in different *genera*. Though generally cartilaginous, these turbinated bones are membranous in the cassowary and albatross, and bony in the calao and toucan.

In the nostrils of REPTILES there are convoluted prominent plates, which, however, are merely membranous productions, unsupported by any bone.

In the FISHES, in like manner, there are membranous folds, the disposition of which is tortuous. They are, however, more regularly arranged than in the other classes. In the cartilaginous fishes they consist of semilunar folds placed in parallel tracts on each side of a broad plate, which divides the one side of the nasal cavity from the other. In the sturgeon, however, they are arranged in diverging plates, which are subdivided into more minute ones, like the branches of a tree. In the osseous fishes generally they consist of radiating plates disposed round a prominent central tubercle.

In these three classes the olfactory nerve is distributed to the membrane much in the same manner. This nerve, however, does not proceed farther than the superior turbinated bones; and the middle and inferior appear to be supplied with filaments of the fifth pair, the naso-ophthalmic branch of which is distributed to the nose in all the vertebrated animals. In the MAMMALIA, further, the spheno-palatine ganglion sends several filaments to the posterior part of the narine membrane.

By most zootomical authors the trunk of the elephant has been described as an organ of smell peculiar to that animal. We are satisfied, however, from observing the motions of this body in the living animal, that it is an organ, not of smell, but of prehension. Cuvier, after adopting the ordinary view, has relinquished it, and, on the ground of personal inspection, admits that the sense of smell in the elephant is confined, as in other animals, to that portion of the nasal cavities which is contained within the bones of the head. The trunk of the elephant, therefore, will with greater propriety be noticed under a subsequent head.

The nasal cavities of the CETACEOUS animals are not so much organs of smell as channels of respiration, and must also be noticed afterwards. It is sufficient here to remark, that in these animals the part of the cranium corresponding to the ethmoid bone is penetrated by no aperture, or, in other words, is not an ethmoid bone. It has therefore been asserted that the CETACEA have no olfactory nerve, and no sense of smell. This, however, is by no means established. Blainville and Jacobsen have observed in the dolphin nerves which they regard as olfacient; and Treviranus delineates nerves of the same character. By Otto and Rudolphi, on the contrary, who have had frequent opportunities of dissecting the dolphin and whale, the existence of these nerves is denied.

Though almost all the invertebrated animals give proofs of the existence of the sense of smell, in none of them do we find any organ in which this sensation appears with certainty to be exercised. That these animals possess the faculty of smell, is inferred from the fact, that insects recognise their food at a distance; that male butterflies scent the female even when inclosed in cages; and that the ordinary flesh-fly deposits her eggs on tainted meat, and occasionally on fetid plants, in the belief that they are the proper *nidus*, though in the latter case the *larvæ* perish for want of the necessary sustenance.

Smell in invertebrated animals.

Since odorous particles are evidently applied to the olfactory membrane of all aeropnoic animals by the medium of the atmosphere, and since the organ of smell is therefore situate in connection with the wind-pipe, it was conjectured by Baster, that, in insects at least, the organ of smell is situate at the entrance of the *tracheæ* or air-tubes. This conjecture derives some probability from the fact, that the inner tracheal membrane in these animals is soft and moist, and that those in which it is expanded into convoluted *lacunæ* and tortuous vesicles, for instance beetles, flies, and bees, are remarkable for the nicety of their sense of smell.

The *antennæ*, in which this sense has been placed by some anatomists, appear to be rather organs of touch than of smell.

In the MOLLUSCA the whole cutaneous covering seems to combine the character of an organ of touch or tact, and of smell. Like an extensive pituitary membrane, it is soft, villous, moist, and liberally supplied with nerves. The ARTICULATA and Zoophytes seem much in the same state. But on all these points information is rather conjectural than positive.

SECT. II.—THE EYES; THE ORGANS OF VISION.

All red-blooded animals, without exception, are provided with two movable eyes, consisting of the same essential parts as those of man, forming globular organs, and placed in the cranio-facial cavities named orbits. In none are there more or fewer; and the exceptions to the general rule, either in relation to the presence of these organs, or number, are only apparent. Among the MAMMALIA, indeed, there are two instances of blindness,—in the *zemni* or blind rat (*Mus typhlus*, Lin.; *Spalax typhlus*, Pall.), and the golden mole (*Talpa Asiatica*, Lin.; *Chrysochloris*, Lacep and Cuvier). But in neither of these animals are

Blind though not eyeless animals.

Comparative Anatomy.

the eyes absolutely wanting; they are merely very minute, and covered by a thin fold of hairy skin, in which there is said to be no aperture. Much in the same manner the *murœna coecilia*, and the hag-fish (*myxine*, Lin., *gastrobranchus cœcus*), though provided with eyes, are deprived of the use of these organs by the opacity of the *conjunctiva*. In the *Anableps* (*Cobitis Anableps*, Lin.), the *cornea* and *iris* are biparted by transverse bands, so as to give the animal the appearance of having two pupils in each eye, though the crystalline lens, vitreous humour, and retina, are single. This animal affords the only example of this structure among the vertebrated animals; but a similar arrangement is observed in the Cephalopodous Mollusca and cuttle-fish family.

Figure of the eye-ball.

The general shape of the eye depends on the medium in which the animal lives. It is nearly spherical, or approaching the spherical shape, in man and the quadrupeds moving along the surface of the earth; that is, in the lowest and most dense region of the atmosphere. The *cornea* merely forms a slight convexity, in consequence of being the segment of a smaller sphere than the rest of the eyeball; yet in the porcupine, opossum, &c., this difference is inconsiderable. To show the degree of this convexity, it is merely requisite to compare the axis or antero-posterior diameter with the transverse diameter of the ball, as exhibited in the following table:—

Axis and diameter.

	Axis.	Tr. Diam.		Axis.	Tr. Diam.
Man and ape	137	136	Whale	6	11
Dog	24	25	Porpoise	2	3
Horse	24	25	Owl	13	12
Ox	20	21	Vulture	13	16

According to the measurements of the younger Soemmering, the axis of the human eye, taken in a beautiful Tyrolese girl of 20, is to the transverse diameter as 100 to 95; that of the eye of the magot (*simia inuus*) as 85 to 84; and that of the bat (*vespertilio auritus*) as 12 to 11. In the raccoon (*ursus lotor*) and lynx (*felis lynx*) alone the axis is exactly equal to the diameter. In all the other vertebrated animals, it is, as in the measurements of Cuvier, less than the transverse diameter at the rate of from 9 to 33 or 45 per cent. In the horse it is as 186 to 212, in the seal as 130 to 142, in the Indian elephant as 135 to 180, and in the black whale (*balœna mysticetus*) as 20 to 29. In the owl it is as 17 to 18, in the golden falcon as $14\frac{1}{2}$ to 16, in the ostrich as 18 to $19\frac{1}{2}$, and in the swan as 7 to 10. In the Reptiles and Fishes it is always less at the rate of from 3 to nearly 10 per cent. In the cuttle-fish, which may be taken as a general example of the invertebrated classes, it is much greater, the axis being to the diameter as 80 to 57. (D. W. Soemmering *de Oculorum Hominis Animaliumque Sectione Horizontali Commentatio*. Goetting. 1818, fol.)

In Fishes and the Cetacea which inhabit the sea, the anterior part of the eyeball is much more flattened, and in many fishes it resembles a hemisphere with the plane surface before and the convex behind. In the ray *genus* the superior part is also flat, so as to give the eye the appearance of the quadrant of a sphere, cut through two large circles perpendicular to each other. In some fishes, especially the burbot (*Gadus Lota*), the *cornea* is convex.

In Birds which occupy the elevated regions of the atmosphere, the deviation from the spherical shape is in the direction opposite to that of fishes. On the anterior part, which is sometimes flat, sometimes shaped like a truncated cone, is chased a short cylinder, closed by a very convex, and occasionally hemispherical *cornea*, always belonging to a much smaller sphere than the posterior convexity.

Aqueous humour.

These differences in shape depend on the proportion between the density of the medium in which the animals live and that of the aqueous humour. In the higher regions of the atmosphere, in which the air is very much rarefied, the refracting power of the aqueous humour is much more considerable than at the surface, occupied by quadrupeds; and hence it is more abundant in the former than in the latter class. Its refracting power, however, would be almost extinguished in a watery medium, from which it could differ but little in density; and hence it is either trifling or absolutely wanting in the inhabitants of the deep. In the cuttle-fish family it is entirely wanting.

The crystalline lens in Fishes, which is nearly spherical, projects through the pupil, and leaves little room for the aqueous humour. The lens is also very convex in the Cetacea, the Amphibious Mammalia, the diving birds, as the cormorant, and the marine and aquatic Reptiles.

Affecting the oblate spheroidal shape in the Mammalia, it becomes extremely so in man, and still more in Birds. Its consistence is greatest in animals in which it is most convex; and hence it is matter of common observation, that the crystalline of fishes is particularly firm. It also contains rather more albumen than the lens of the Mammalia. The crystalline lens occupies least proportional space of the eyeball in man, and most in fishes.

The comparative spaces occupied by each of the humours may be understood from the following table, in which the axis of the eye, or the space occupied by the whole three humours, is represented by unity.

	Aqueous Humour.	Crystalline Humour.	Vitreous Humour.
Man	$\frac{5}{22}$	$\frac{4}{22}$	$\frac{15}{22}$
Dog	$\frac{5}{21}$	$\frac{8}{21}$	$\frac{8}{21}$
Ox	$\frac{5}{37}$	$\frac{14}{37}$	$\frac{18}{37}$
Sheep	$\frac{4}{17}$	$\frac{11}{17}$	$\frac{12}{17}$
Horse	$\frac{9}{43}$	$\frac{16}{43}$	$\frac{18}{43}$
Owl	$\frac{8}{27}$	$\frac{11}{27}$	$\frac{8}{27}$
Herring	$\frac{1}{7}$	$\frac{5}{7}$	$\frac{1}{7}$

On the proportion of the total volume occupied by each of the three transparent parts there are few accurate facts. It may be remarked, however, that the human eye among the Mammalia is that in which the vitreous humour is proportionally most abundant. It is estimated to be twenty times more copious than the aqueous. In the ox it is only ten times, and in the sheep nine times the quantity of the aqueous.

Sclerotic.

In the Mammalia generally, the sclerotic is comparatively elastic, soft, and yielding; but in all animals in which the eye deviates from the spherical shape, as the Cetacea, Fishes, and Birds, this membrane is strengthened by greater solidity and thickness of tissue, or supported by accessory parts of a hard unyielding structure.

In the eye of the whale these two parts, the hard and soft, are naturally distinguished in a very striking manner. The lateral parts of the sclerotic are nearly an inch thick, and very hard. The posterior part is about one and a half inch thick, and softer, because the spaces between the firm fibres are filled with oily substance. The posterior part presents for the optic nerve a canal one and a half inch long, the walls of which are formed chiefly by fibres in direct continuity with the *dura mater*,—the only fact, it may be observed, which favours the statement of the ancient anatomists, that the sclerotic is derived from the *dura mater*. The sclerotic of the porpoise, though only two or three lines thick, has the same structure as that of the whale. In the seal it is thick before and thicker behind, but the middle zone is thin and flexible.

Osseous zone of birds.

The sclerotic in Birds is thin, flexible, and elastic behind, with a bluish glistening aspect, and without distinct fibres. The optic nerve enters, not by a hole, but an oblique canal. The anterior part consists of two plates, between which is enchased a zone of thin, hard, oblong, osse-

Comparative Anatomy.

ous scales, varying in number from 11 or 12 to 14 or 15, imbricated over each other so as to give the anterior part of the eyeball a great degree of hardness, and a figure unsusceptible of change. Though these plates are nearly flat in most birds, and form an annular zone slightly convex, they are broad, arched, and concave internally in the owl *genus*, and form a bell-shaped tube, with the posterior aperture oval and the anterior round. This may be denominated the osseous ring (*annulus osseus, zona ossea*). In the ostrich it is narrow and flat.

and reptiles.

Among the REPTILES, the CHELONIADS possess an osseous zone, consisting of plates inclosed in the membrane without being continuous with its substance. They are also found at the lateral part of the sclerotic in the chameleon and some of the SAURIAL Reptiles, as the *Crocodilus Sclerops* and *Lucius*, the monitor, and the iguana (D. W. Soemmering). It is also an important character in the structure of the eye of the Ichthyosaurus, which indicates the connection of that animal with the SAURIAL tribe, that its sclerotic was provided with an osseous zone, consisting, as in these, of 13 separate pieces.

In FISHES the sclerotic is cartilaginous, homogeneous, semi-translucent, elastic, and, though thin, firm enough not to collapse. In the ray it is expanded into a tubercle, by which the eye is attached to a peduncle or stalk. The sclerotic of the sturgeon is so thick that it resembles a cartilaginous sphere, with the external part hollowed for the humours and membranes.

In the CEPHALOPODOUS MOLLUSCA it forms behind a truncated cone, with the apex at the bottom of the orbit containing the gangliform swelling of the optic nerve, and several glandular parts, with the eye before.

Cornea.

The *cornea* has often been represented to be merely a continuation of the sclerotic; and though this is easily disproved by accurate dissection of the human eye and that of our ordinary domestic animals, its inaccuracy is much more manifestly demonstrated in the animal world at large. In the whale and rhinoceros the margins of the two membranes penetrate reciprocally. In man and the ox the corneal margin is enchased within the sharp imbricated edge of the sclerotic. In the tope-fish (*squalus milandra*, Lin.; *galeus*, Cuv.) the cornea is observed distinctly passing within the sclerotic in the manner of imbrication. The cuttle-fish is destitute of cornea; and as there is no aqueous humour, the crystalline lens is covered by a fine thin membrane, extended beneath the conjunctiva.

Corneal conjunction.

In all animals provided with eyelids, the mucous membrane, after being folded behind the eyelids, is reflected forwards over the sclerotic and cornea, in the form of a thin, transparent membrane. In those void of eyelids, as most fishes are, the skin, passing into mucous membrane, is continued directly over the *cornea*, without forming any angular fold, and adheres strongly. This is very distinct in the eel, which may be flayed without leaving any trace at the site of the eyes, except a round, translucent spot. The same peculiarity is remarked in SERPENTS and in the cuttle-fish family. In the *zemni*, golden mole, blind eel, and hag-fish, it has been already stated that the cornea is covered by opaque mucous membrane.

Choroid coat and Ruyschian membrane.

The choroid coat exists in all animals yet examined. It is always very vascular. The inner layer, which has been distinguished by the name of *tunica Ruyschiana*, can scarcely be said to exist in man, small quadrupeds, and birds. In the large quadrupeds, however, especially the CETACEOUS animals, it appears in the form of a distinct simple membrane like *epidermis*. The lateral and anterior parts of the membrane are always invested by a semifluid, viscid substance, of different shades of black or brown black (*pigmentum nigrum*); chocolate brown in the hare, rabbit, and pig; deep red brown in some birds; and purple red in the *calmar*. The absence of this dark-coloured pigment, which is not unfrequent, is observed in *albinos*, both human and animal, for instance white rabbits and white mice. The transparency of the Ruyschian membrane then shows the choroid of its natural red colour; and the pupil is red and contracted, and the eye intolerant of light.

The tapetum or metalline membrane.

In the ZOOPHAGA, RUMINANTIA, PACHYDERMATA, SOLIDUNGULA, and CETACEA, the concave or inner surface of the Ruyschian membrane is diversified with colours of metallic lustre, more or less brilliant and something iridescent. In the ox it is of bright metallic green, changing to sky-blue; in the horse, buck, buffalo, and stag, it is a silvery blue passing to violet; in the sheep of a pale golden green, sometimes bluish; in the lion, cat, bear, and dolphin, of a pale gold yellow; and in the dog, wolf, and badger, of a pure white, surrounded by blue. This coloured part of the inner choroid surface, which occupies chiefly the side opposite to that on which the optic nerve enters, is named the *tapetum*. The use of it is by no means obvious. The explanation of Monro in reference to the *tapetum* of the ox, that it represents more distinctly to that animal the colour of his natural food, is not only frivolous, but inapplicable to the other *genera*.

The *tapetum* is wanting in all BIRDS and FISHES, excepting the ray, in which there is at the bottom of the eye a beautiful silvery-coloured space, produced by the transparency of the Ruyschian tunic, through which the tint of the choroid is seen.

The choroid gland of fishes.

In FISHES generally the choroid consists of two distinct separable membranes; the external, the proper choroid, white, silvery, or golden, very thin and not vascular; and the inner or Ruyschian, black, and consisting of a network of vessels. Between these two membranes is a body of a bright red colour, consisting of numerous tortuous vessels, convoluted and inclosed in pulpy filamentous tissue. Its general shape is that of a thin cylinder, encompassing the optic nerve like a ring, which, however, is incomplete at one side. This is the choroid gland,—a body about which there has been some difference of opinion, but which appears to be glandular rather than any thing else. Its vascular structure is well seen in the globe-fish, *perca labrax*, and cod, in which they are very large, and form numerous anastomotic communications. They are generally covered by a white, opaque, viscid fluid.

The choroid gland is wanting in the CARTILAGINOUS FISHES, the eye of which approaches more nearly to that of the MAMMALIA in this as in other circumstances. The choroid of the ray and shark *genera* is a threefold tissue of vessels, thick and consistent; the *tunica Ruyschiana* is very thin and semi-transparent; and between these is a layer of silvery matter with metallic lustre.

In the cuttle-fish genus, though between the sclerotic and choroid there are several glandular bodies, there are none between the choroid and Ruyschian tunic. The choroid is thick, soft, and vascular; the Ruyschian thin, firm, and dry; and though there is no *tapetum*, the whole interior surface of the eye is covered by deep purple, semi-fluid, viscid varnish.

Ciliary processes and circle.

Ciliary processes are found in all the MAMMALIA, BIRDS, several REPTILES, and even in the cuttle-fish among the MOLLUSCA; but they are wanting in almost all fishes.

The indented border of these processes is more distinct, and is converted into a genuine fringe in the large animals, as the ox, horse, rhinoceros, and whale, in which the angle applied to the capsule is more acuminated than in other animals. In the CARNIVORA, particularly the lion, the base of the plates is shorter in proportion to the other sides than in the previously mentioned animals, so that the opposite angle is more prominent; nor is the

Comparative Anatomy.

border indented. In all the species every third or fourth plate is shorter than the others, but without determinate order.

The ciliary plates of BIRDS are mere serrated *striæ*, without sufficient prominence to make them undulate in fluid. In the owl they are fine, closely set, and numerous; in the ostrich they are larger and more numerous; and in all, their extremities adhere firmly to the capsule of the lens.

In the tortoise the ciliary processes are so short that they are recognised only by the impression left on the vitreous humour; in the crocodile, however, they are distinct, and terminate each by an angle nearly right. They are indistinct in the toad, and imperceptible in the ordinary lizards and serpents.

The ciliary body and processes are large and distinct in the tope-fish; but if they are seen in any other of the cartilaginous fishes, they are wholly wanting in the osseous, in which the Ruyschian tunic is directly continuous with the *uvea*.

The utility of these processes in retaining the lens in its position is nowhere so distinctly seen as in the eye of the cuttle-fish family, and especially the many-feet of the ancients (*polypus octopoda*). In these the ciliary processes form a large diaphragm or zone, in the aperture of which the crystalline lens is truly chased. They penetrate a deep annular furrow which surrounds the lens, dividing it in two unequal hemispheres, and cannot be detached without laceration.

The iris and uvea.

The *iris*, of the same intimate structure as in man, is of a deep tawny or brown in the MAMMALIA, and marked with fewer coloured *striæ* than the human *iris*. In BIRDS it is of a uniform lustreless colour, varying according to the species, bright yellow, red, or clear blue. In the microscope it appears like a net-work formed by the intersection of numerous very minute fibres. The *uvea* is so fine that when the viscid varnish is removed it becomes transparent, and the iris appears of the same colour on both sides. In FISHES, conversely, the *iris* is so thin and transparent that the *uvea* is seen through it, of a golden or silvery brilliance, showing its direct connection with the choroid. Intermediate in metallic splendour is the iris of the REPTILES. The vessels, however, are greatly more conspicuous, especially in the crocodile.

The central aperture or pupil, though round in man, the QUADRUMANA, many of the CARNIVORA, and BIRDS, is not of that shape when contracted in all animals. In the feline family it consists of two elliptical segments, which form angles above and below, and which approach mutually so as to form a slit nearly vertical. In the RUMINANTS it is oblong transversely, and forms at its greatest contraction an oblong or transverse slit. In the horse, in which it is also transverse, its upper margin is distinguished by a five-pointed festoon. In the whale it is oblong transversely, and in the dolphin it is heart-shaped. The pupil of the crocodile resembles that of the cat; in the frog and gecko it is rhomboidal; and round in the tortoise, chameleon, and common lizards. In the ray among FISHES the upper margin forms several radiating slips like the branches of the palm-tree, gold-coloured without, dark within. In the dilated state these slips are folded backwards between the upper margin of the pupil and the vitreous humour; but when the eye is pressed they are erected, and close the pupil like a blind.

The motion of the pupil is voluntary in the parroquet, and is indistinct in most of the FISHES.

The pupillary membrane is well known to exist in the fœtuses of all the MAMMALIA; but it is not determined whether it is found in the chick of birds.

On the subject of the retina in the lower animals the most important point is the structure of the melanoplectic or pectiniform membrane (*pecten, marsupium nigrum*) of BIRDS. In this class the optic nerve forms not a round disk as in the MAMMALIA, but a narrow white line, the margins and extremity of which are in continuity with the *retina*. Along this line is suspended a plicated or convoluted membrane, very fine and vascular in structure, like the choroid, from which, however, it is quite distinct, and entering a depression of the vitreous humour almost like a wedge. Its vessels, which proceed from a proper branch of the ophthalmic artery, are distributed in a minute arborescent form, among the folds of which the *marsupium* consists; and from these vessels the black viscid pigment with which its folds are covered appears to be secreted. The *plicæ* or membranous folds vary in number. In the cassowary they are only 4; in the brown owl (*S. aluco*) 5; in the common owl, ostrich, Guiana macaw, and merganser, they are 7; in the flamingo 9; in the falcon and swan 11; in the vulture and goose 12; in the duck, large heron, woodcock, and coot, 13; in the stork and partridge 15; in the crane 17; in the pheasant 20; in the turkey 22; in the jackdaw 25; and in the thrush 28. According to the observations of the elder Soemmering, to whom we are indebted for these numbers, the number of folds, though variable in different species, is the same in the same. In most birds the folds are arranged in a pectiniform order. On the use of this organ different opinions have been entertained by Petit, Haller, and Home; but all of them are conjectural.

The melanoplectic membrane, or *marsupium nigrum*, and its folds.

In the REPTILES and many FISHES, between the optic nerve and the *retina* is a small tubercle, from the margins of which the latter membrane appears to rise; and radiating fibres are perceived more distinctly than in most quadrupeds. In many other FISHES the connection of the retina with the optic nerves resembles that of BIRDS. Thus, in the salmon, trout, herring, mackarel, cod, dory, and moon-fish, the optic nerve, after passing through the Ruyschian tunic, appears to be parted into two long white processes, which, following the outline of this membrane parallel but not contiguous to each other, are connected with the *retina* by their opposite margins.

In all animals provided with ciliary processes the *retina* terminates at and is connected with the gray pulpy zone denominated ciliary ligament. In those without ciliary processes, as the FISHES, it terminates suddenly at the attached or large margin of the *uvea*.

In several of the reptiles the retina presents the yellow spot of Soemmering. The principal peculiarities of the humours have been already mentioned.

Of the appendages the most important are the lacrymal gland and nictitating membrane.

Lacrymal gland.

In the Ruminants the lacrymal gland consists of two or three bodies, each composed of granules, each provided with a separate short excretory duct. In the hare and rabbit, in which the gland is large, there appears to be only one excretory duct, which perforates the upper eyelid near its posterior angle.

A gland peculiar to certain species, and wanting in man, that of *Harder*, is situate at the external or nasal angle, and presents an aperture under the third or nictitating eyelid, from which issues a thick viscid fluid. It is found in the RUMINANTS, the RODENTIA, the PACHYDERMATA, and in the sloth genus.

The caruncle exists in the RUMINANTS as in man, and appears to consist of numerous aggregated follicles. It is wanting in the RODENTIA.

In the CETACEA, as in most animals which live under water, there is neither gland nor lacrymal passages; and they are represented apparently by *lacunæ* below the upper eyelid, which discharge a thick mucilaginous fluid.

BIRDS, though destitute of caruncle, have both lacry-

Comparative Anatomy.

mal gland and that of Harder, the latter large, oblong, and flesh-coloured, placed betwixt the *levator* and *adductor*, and discharging by a single canal, opening at the inner surface of the third eyelid, a thick yellow fluid. The lacrymal, which is small, round, and very red, is provided in general with two or three canals, which, though small, are distinct. In most of the GRALLÆ and PALMIPED Birds there is, in place of the lacrymal gland, a hard granular body, occupying the upper part of the orbit, and following in situation the curvature of the eye. It has, nevertheless, no visible excretory duct.

Muciparous follicles.

In the turtle there is a reddish granular lobulated body, of considerable size, extending beneath the temporal vault. In the tortoise, frog, and toad, there are two small blackish glands without apparent excretory ducts. Neither in Serpents nor FISHES has any glandular apparatus in the eye been recognised.

The third eyelid or nictitating membrane.

Though in man and the monkey tribe the eyelids consist of two semilunar cutaneo-muscular folds, with a minute mucous duplicature at the nasal angle, the latter acquires such a developement in the lower animals as to constitute a genuine third eyelid, often distinguished by the name of *nictitating membrane*. This duplicature is semilunar in shape in the Ruminants, EDENTATA, and PACHYDERMATA. In the rhinoceros it is thick and fleshy; but of this the CETACEA present no trace. In the BIRDS, on the contrary, in which the eye is covered by the elevation of the lower eyelid, which is also the largest, the third eyelid is large, and covers the eye like a blind drawn before it; yet it is in some degree translucent, for it is evident that birds see objects through the membrane. In the owl and goatsucker the eye is closed by the depression of the upper as well as the elevation of the lower eyelid.

Though the SERPENTINE reptiles are void of eyelids entirely, in the crocodile, tortoise, and BATRACHOID, there are three, as in birds, the third being vertical in the two former orders, and horizontal in the latter. In the SAURIAL and CHELONIAD, also, the third, which is translucent, moves from before backwards by means of a single muscle, and may cover the whole eye. In the lizard *genus* the eyelids consist of a circular veil drawn before the orbit, and perforated by a horizontal fissure, which is shut by a *sphincter*, and opened by a *levator* and *depressor*. The gecko has no movable eyelid.

Compound eyes of the ARTICULATA.

In insects, the eye consists of innumerable hexagonal surfaces, slightly convex, and mutually separated by minute furrows, containing fine hairs variable in length. Each of these hexagonal surfaces, which constitute a hard, elastic, very transparent membrane, may be regarded as a cornea or crystalline lens, convex externally, concave within, and thicker in the centre than on the margins. Immediately behind is an opaque, viscid coating, varying in colour in the different species, analogous to the choroid pigment of the vertebrated animals, and completely obstructing the transmission of light. Beneath this varnish are short, whitish filaments, corresponding in number to the corneal surfaces, and mutually joined like mosaic or tessellated pavement, separated only by the dark-coloured pigment, and which appear to correspond to the *retina* of the VERTEBRATA. Behind these again is a delicate, dark-coloured membrane, which appears to correspond to the choroid; and exterior to this is a membrane continuous with the optic nerve, and which seems to be a *general retina*, forming, by subdivision of its parts on the anterior part of the choroid, the *divided* or multiplied *retina*. This is the structure of what are named *compound eyes*. That of the simple eyes of insects is too minute to be accurately demonstrated; but analogy gives probability to the inference that they are not dissimilar.

SECT. III.—THE EAR.

Comparative Anatomy.

In warm-blooded animals generally, that is, in the MAMMALIA and BIRDS, the labyrinth or essential part of the organ consists of three semicircular canals, with a globular enlargement to each (*ampulla*), a cavity common to these canals named vestibule (*vestibulum*), and a conical tapering canal, divided into two compartments by a longitudinal *septum*. This may be named the bilocular cone (*conus bilocularis*). These parts consist of membranous substance inclosed in the bony walls of the pyramidal or auditory bone. In all the MAMMALIA the bilocular conical canal is convoluted in a spiral form, and hence is denominated, as in man, the *cochlea*—a name, however, which is applicable to it in this class only.

Cochlea and canals.

The organ of hearing in the MAMMALIA consists of the same parts nearly as in man. In some, indeed, for instance the guinea-pig (*cabiai*), and porcupine, the *cochlea* makes three turns and a half; and, conversely, in the CETACEA only one and a half. In most of the ZOOPHAGA, and in the hog, elephant, and horse, the *cochlea* is much larger in proportion than the semicircular canals; but in the hare it is small, and in the mole very small. In the CETACEA, while the *cochlea* is very large and fully developed, its spiral is on the same plane throughout; and the semicircular canals are so small, that their existence was long denied by Camper, till they were demonstrated by Cuvier in a fœtal whale. In general the labyrinth of the MAMMALIA is greatly smaller in proportion to the head than in BIRDS.

This part, which is membranous, is inclosed in the solid compact substance of the temporal pyramid, so closely that its existence appears to be identified with the latter. Researches, however, on the labyrinth in the fœtus of the MAMMALIA, and especially in those of whales, demonstrate the fact that it is in a completely membranous form, distinct from the bony inclosure; that in shape and constituent parts it exists previous to the bony inclosure; and that the latter is afterwards moulded round the different parts as they acquire their full developement. It is also to be observed, that in the mole the semicircular canals are seen within the cranium without preparation, and the *cochlea* is merely inclosed in fine cellular tissue. In the bat family, also, both parts are seen without bony inclosure.

Tympanum.

The tympanum forms a cylindrical or spheroidal cavity in most of the MAMMALIA. In most of the DIGITATA the mastoid process consists of a slight prominence of the *tympanum* only as it is identified with the latter; but in the *cabiai*, guinea-pig, hog, the Ruminants, and SOLIDUNGULA, it is represented by a long process of the occipital bone. In most of the ZOOPHAGA and RODENTIA the *parietes* of this protuberance, which are thin and hard, form by their separation a large cavity. In the hog only it is occupied by a firm cancellated structure.

Tympanal bones.

All the MAMMALIA, except the *ornithorhyncus*, have the tympanal bones as in man; the hammer (*malleus*), anvil (*incus*), orbicular bone and stirrup (*stapes*). The lenticular bone, which is rarely found in the adult, is probably only an epiphysis of the anvil. They are articulated with each other so as to admit of motion, and are moved by the same muscles as in the human subject—the *internus mallei*, *externus mallei*, *laxator tympani*, and *stapedius*. In the *ornithorhyncus*, however, there are only two tympanal bones.

External aperture.

In all the MAMMALIA, except the Cetaceous, the ear is provided with a bony external canal (*meatus*); and most of the MAMMALIA, except the Cetaceous, have a cartilaginous funnel-shaped opening (*concha*) attached to the outer margin of the bony *meatus*, and which serves to

Comparative Anatomy.

collect the sonorous vibrations, and direct them to the *meatus*. The other exceptions are among the INSECTIVORA, the mole, and some of the shrew *genus;* among the RODENTIA, the *zemni* or blind rat, and some of the rat-mole *genus;* among the EDENTATA, the pangolin or scaly ant-eater; and among the AMPHIBIA, the morse and several species of seal; and the *ornithorhyncus paradoxus*.

The *tympanum* of the CETACEA is peculiar. It consists of a bony plate, convoluted on itself like a *buccinum*, unless that the thick side, instead of containing a spiral cavity, is entirely solid. The opposite side is thin, with an irregular margin. The anterior extremity of the *tympanum* is open, and there commences the Eustachian tube, which ascends along the pterygoid process, and, penetrating the maxillary bone, terminates at the upper part of the nose. This direction of the tube and position of its orifice is so much more necessary, because, since these animals have no external bony *meatus*, and the ear-hole scarcely admits a pin, the vibrations of the air reach their organ of hearing entirely by the Eustachian tube, and because the Eustachian tube also in these animals conveys odorous impressions to the part in which the sense of smell appears to reside. The aperture by which it communicates with the nose is provided with a membranous valve, which prevents the water from entering when the animal expels it by his nostrils.

In BIRDS, of the three semicircular canals the vertical is largest, and obliquely directed forwards and outwards; the second is horizontal and turned outwards; and the third, which, like the first, is vertical, crosses the second, and is turned in the direction opposite to that of the first. The vestibule is small and nearly spherical. The bilocular cone, which is obtuse at the *apex*, is situate obliquely backwards and outwards below the inferior part of the cranium. The longitudinal septum consists of two narrow cartilaginous plates connected by a thin membrane. The posterior canal is short, and, as in the MAMMALIA, is separated from the tympanal cavity by the membrane of the *fenestra rotunda;* while the anterior, which is larger, communicates directly with the vestibule. The whole of these parts are inclosed, as in the MAMMALIA, in the compact bone of the pyramid.

Bilocular cone no longer spiral.

The posterior and inferior walls of the tympanal cavity are formed by part of the occipital bone; the lateral aperture is large, and the cavity superficial; and its anterior part is closed by the posterior superior *cornu* of the quadrilateral bone and a membrane. The inner wall presents the two apertures—the oval or vestibular, and the round or cochlear. In this class, however, while the upper is round or triangular, the lower is distinctly elliptical,—a disposition the reverse of what is observed in man. The Eustachian tube or tympano-guttural canal is entirely osseous. The tympanal cavity contains only one *ossiculum*, consisting of two branches; the first attached to the tympanum, corresponding to the *malleus;* the second closing by an oval or triangular plate the vestibular aperture, and therefore corresponding to the *stapes* of the MAMMALIA. By Carus the incus is supposed to be represented by the quadrilateral bone.

Tympanal bones disappearing or modified.

The external *meatus* is short, and opened by a simple aperture, while the absence of external ear is compensated by a ring or zone of fine elastic feathers with thin barbs, between which the air passes very easily. In the owl tribe it terminates in a large cavity, the margins of which are covered by a smooth valvular fold of skin.

Bilocular cone disappears.

The ear of the REPTILES is remarkable for the last appearance of the bilocular cone, and the first of the saccular apparatus which is found in the Fishes. In the crocodile and lizard this part appears, as in Birds, in the shape of a conical tube, divided by a cartilaginous partition into a double canal, one separated by the membrane of the round hole from the tympanal cavity, the other communicating with a membranous sac containing three very small friable stones, not harder than starch. There are also three semicircular canals of considerable size, each forming a large circumference. In the frog and toad, while the three canals form almost a complete circle, the sac contains an amylaceous friable stone; but the bilocular cone is no longer observed. In the salamander, also, in which the three canals form together a sort of equilateral triangle, the sac which is below contains a single amylaceous stone. The same arrangement is observed in the Cartilaginous Fishes, unless that the sac contains two amylaceous stones, nearly oval in shape, suspended in a gelatinous semifluid pulp. In the Osseous Fishes it is a little different. The three semicircular canals terminate in a membranous sac, which is divided by septa into compartments which contain one, two, or three small stones suspended in gelatinous fluid. These minute stones, however, instead of being soft, friable, and amylaceous, as in Reptiles and cartilaginous Fishes, are as hard as rock, and white as porcelain. These parts are situate on the sides of the cranial cavity, and are fixed to it by cellular tissue, vessels, and osseous or cartilaginous processes. This sac, in the fluid of which the extremities of the auditory nerve are distributed, is believed to correspond to the bilocular cone of the higher classes.

Lithophorous sacs and amylaceous stones appear.

These membranous cavities are contained, in the bony fishes, in the general cavity of the cranium; and while only the middle of the canals is inclosed in the bone of the cranium, the extremities and the sac are quite free. The sturgeon, which belongs to the cartilaginous order, is the first in which the canals are entirely inclosed in the cranial cartilage; but even in this a membrane is interposed between the cranium and sac, which is free. In the ray and shark *genera*, again, these organs are entirely inclosed in the cartilage of the head.

The tympanal cavity, in like manner, is modified, and eventually disappears as we descend in the scale. Though present in the tortoise, crocodile, and lizard tribe, it is superficial and open; it becomes membranous behind in the RANINE tribe, and communicates directly with the back of the mouth; and in the SERPENTINE reptiles it entirely disappears, so that the handle of the osseous plate by which the oval aperture is closed is suspended in the soft parts with its free extremity below the skin, near the articulation of the lower jaw. In the lizard tribe, also, the round or cochlear aperture is seen for the last time. In the Cheloniad, for instance, the Batrachoid, and the Serpentine, this aperture disappears, and the oval or vestibular alone is left; and in the salamander both disappear, and there is no communication between the external part of the cranium and the labyrinth. This arrangement is continued in the fishes.

Cochlear aperture disappears.

Vestibular aperture disappears.

In the molluscous animals the labyrinthine membrane is a simple sac, globular or ovoidal, containing pulpy matter, in which is suspended a small body, which is osseous in the *sepia* and amylaceous in the many-feet (*polypus*), in which the filaments of the auditory nerve are distributed.

Our limits do not allow us to enter into the detailed description of the organ in the other INVERTEBRATED animals.

SECT. IV.—THE ORGAN OF TASTE.

Though the sense of taste is seated chiefly in the tongue in animals, yet that organ performs, in all the classes, so important a part as an instrument of prehension, that it cannot with much justice be distinguished by the former title only. In the present section, therefore, we must regard it as one of prehension as well as of taste.

Comparative Anatomy.

The tongue.

In the MAMMALIA and BIRDS the tongue is a muscular organ invested by mucous papillated membrane, supported by a proper bone, the hyoid, which serves as a point of support in its various motions. In the RANINE REPTILES it is also muscular, attached to the margin of the lower jaw. In the salamander, however, it is attached as far as the tip, and is movable on the sides only. In the crocodile it is attached so generally, both by tip and margins, that it was long asserted that the animal was tongueless. In the *stellio* and *iguana* it is as movable as in the MAMMALIA; and in the scinc and gecko to this property is added that of being bifid, or divided by a longitudinal notch into two pointed tips. In the ordinary lizard, tupinambis, monitor, &c. the tongue is remarkable for its great extensibility, and terminates in two long, flexible though semi-cartilaginous extremities. That of the chameleon is still more extensible, and forms, by a peculiar arrangement of vessels, a cup-like extremity. The tongue of the blind worm (*anguis fragilis*) and *amphisbœna* is also bifid at the tip. The cartilaginous fishes are void of tongue, while in the bony division of the class this organ is represented by a hard protuberance, attached to the middle branchial bone.

In some of the MAMMALIA, however, the tongue is not exclusively muscular. In the singularly long, extensible, and tortuous tongue of the giraffe, Sir Everard Home describes a peculiar arrangement of vessels, which he represents as a substitute for muscular motion. Though Sir Everard does not appear to understand the exact nature of this arrangement of vessels, all the circumstances tend to show that it is that denominated erectile. These vessels, from the account given, are large, numerous, and communicate freely; and it would be impossible to discover the reason of such a vascular system, unless for some purpose of this description. (*Phil. Trans.* Comp. Anat.) When the tongue is protruded it becomes perfectly black or bluish-black, evidently from the injection and detention of the blood in its elongated and anastomosing veins. By means of this mechanism the giraffe not only elongates the tongue to the distance of about twenty inches or two feet beyond the mouth, but twists it round the soft leafy twigs of the trees on which he feeds. It is not improbable that a similar vascular arrangement exists, though in less degree, in the tongue of the deer, and in the long projectile tongue of the animals of the ant-eater tribe, as the *Tamanoir*, *Tamandua*, &c.

Erectile arrangement in the tongue of the giraffe,

and of the chameleon.

The erectile arrangement is still more distinctly presented in the tongue of the chameleon. The researches of Mr Houston of Dublin show that the tongue of this animal consists of two parts,—a prehensile, which is anterior, and provided with a glandular apparatus for secreting the viscid fluid by which its tip is covered, and insects are entangled; and an erectile, which is posterior between the prehensile and the hyoid bone, in the form of a trellis-work of innumerable minute anastomosing blood-vessels, not very dissimilar to those of the cavernous body in animals generally, and inclosing a central tube connecting the prehensile portion to the hyoid bone. The effect of this arrangement is, that when the vascular network is injected with blood, the anterior part of the tongue is rapidly darted out at the insects on which the animal lives. The injection of these vessels, and the consequent projection of the tongue, is not independent altogether of the will of the animal; for the veins by which the blood is returned pass through a slit in the tendon of the internal cerato-maxillary muscles, which are always contracted in order to protrude the hyoid style, and thereby tend, by compressing the veins, to inject the erectile part, and project the tongue. (*Trans. R. I. Acad.* 1828, and *Dublin Hospital Reports*, vol. v. p. 487.) The same arrangement is in all probability found in several of the lizards, the tongues of which, like that of the chameleon, are darted out suddenly, and become of a dark-blue colour at the moment of projection.

Papillæ

In all the MAMMALIA the tongue is invested by a papillated muco-villous membrane, in which the papillæ are of the same general characters as in man—granular, mushroom-like, or fungiform, tubercular or calycoid, and conical or acuminated. The only differences consist in the size and abundance of the fungiform *papillæ*, in the number of the calycoid and the mode of their arrangement, and in the shape of the conical papillæ and the mode of their termination. In the Ruminants especially, the conical papillæ are numerous, long, slightly incurvated, and each terminating in a horny but flexible style slightly incurvated backwards. The tongue of the dolphin and porpoise, examined even by the microscope, presents no distinct conical papillæ, but is covered by minute eminences, each penetrated by a small aperture.

Worm of the dog; its absurdity.

In the tongue of the dog *genus* there is a ligamentous substance extended longitudinally from the hyoid bone to the tip of the member. This, which has been vulgarly distinguished by the name of *worm* of the tongue, and has been absurdly supposed to be the seat of hydrophobic *rabies*, is merely a central pillar of support for the muscular fibres to act with greater steadiness and effect, and which enables the animal to protrude and expand the tongue in lapping water or other fluids better than he could have otherwise done. A similar central ligament is found in the opossum.

The tongue of BIRDS is generally more or less horny, and almost cartilaginous. That of the woodpecker and wryneck is peculiar in consisting of two parts,—a basilar or posterior, loose and fleshy; and an anterior projectile, long, smooth, acuminated, and covered laterally with four or five stiff spines directed backwards, which make the organ a sort of barbed arrow. The soft, loose, or basilar part of the tongue contains the aperture of the glottis; and the surface is covered with minute spines pointed backwards, and each of which is placed in the centre of a fleshy *papilla*.

Trunk of the elephant.

As a prehensile organ of very singular construction, the trunk of the elephant deserves particular notice; and it cannot be more conveniently introduced than under the present section, since it is used not only to convey food, but drink, into the mouth. The trunk may be described as a cylindrical tubular organ, consisting of integument, a sort of fibro-cartilage, muscles, fat, and a membrane of villous character internally. This tube contains two long canals continued from the nostrils, parallel to the axis of the trunk, and separated throughout by a partition of adipose substance about two fifths of an inch thick. From the extremity to the middle part of the intermaxillary bone, in which the tusks are fixed, these canals are nearer the anterior-superior than the posterior-inferior part of the tube, the latter wall being thickest; and their diameter is the same throughout. At this part they undergo a sudden incurvation, approaching the anterior surface of the intermaxillary bone, and form a semicircular bend with the convexity turned forwards. Here also they are so narrow that, without a muscular effort on the part of the animal to dilate them, fluids could not ascend beyond this point; and hence this forms the only valvular contrivance, either to impede the progress of fluids upwards, or to propel them downwards, at the will of the animal.

Above this curvature each canal is dilated before the upper part of the intermaxillary bone, and again is contracted where it bends back to enter the bony nostril; and the curvature is protected before by the nasal cartilage, which is oval, convex in the male, and flat in the female.

Comparative Anatomy.

Both canals are lined by a dry, greenish-yellow coloured membrane, marked with superficial intersections (*rugæ*), inclosing rhomboidal spaces, and some venous branches.

Muscular apparatus of the trunk highly complicated.

Though the muscular *fasciculi* of the trunk are numerous, they may be referred to two orders,—those forming the substance or inner part of the organ, and those by which it is invested. The former, which are transverse, and cut the *axis* in different directions, consist of numerous small muscular packets proceeding in various directions, some running from the inner membrane to the circumference of the tube, others directly from right to left, and others crossing the two former obliquely. All these little muscles are inclosed in cellular tissue, containing white homogeneous fat; and all of them terminate in slender tendons, some of which cross the layers of the longitudinal muscles in their course to the external covering, while others are attached to the internal membrane. Cuvier calculates the number of these minute transverse muscles in the trunk of the elephant to be not fewer than 30,000 or 40,000. (Plate XXXVII. fig. 13.)

The longitudinal muscles, which are external, may be distinguished into anterior, posterior, and lateral bundles. The first extend from the anterior surface of the frontal bone, above the nasal bones and cartilages, in parallel bundles, connected by tendinous intersections downwards on the trunk. The posterior extend from the posterior surface and inferior margin of the intermaxillary bones, and form two layers which meet on the median line along the lower surface of the trunk. The lateral muscles form two pairs, one of which, descending between the anterior and posterior muscles to the middle of the trunk, may be regarded as a continuation of the orbicular muscle of the lips, or the representative of the *nasalis labii superioris;* while the other, which is attached to the anterior margin of the orbit, and is expanded over the root of the former, may be supposed to correspond to the *levator* of the upper lip.

The whole of these muscles are supplied by a very large branch of the infraorbital or second branch of the trifacial nerve, which, entering on each side between the lateral and superior muscle, is distributed to the whole of the trunk.

With such a construction, it is not difficult to understand the numerous motions of the elephant's trunk. While the longitudinal muscles are employed either to shorten the tube, to bend it upwards or downwards or to the side, or by means of the tendinous intersections to give it peculiar inflections, it is manifest that the transverse ones, which act as antagonists to the longitudinal, may also either dilate or close the canals, or incurvate or alter the direction of particular parts.

Vacuefying apparatus in the feet of certain animals.

The foot of the *Lacerta Gecko* and the house-fly presents a prehensile apparatus of peculiar construction for walking along surfaces, in opposition to the action of gravity. In the former animal the plantar surface of each toe presents sixteen transverse slits, leading into an equal number of pouches, which by means of appropriate muscles are capable of forming an equal number of *vacua*, so that the atmospheric pressure is employed with muscular effort to support the animal in his unnatural position. A similar apparatus is found in the upper surface of the head of the sucking fish (*echeneis remora*); and something approaching to it, though less distinctly, in the foot of the walrus. (Home, *Phil. Trans.* 1816.)

CHAP. IV.—COMPARATIVE ANATOMY OF THE ORGANS OF VOICE.

Under this head our limits allow us to mention very few circumstances.

In the American long-tailed monkeys (*sapajous*) the cuneiform cartilages form, by means of adipose cellular tissue, before the upper extremity of the ventricle of the *glottis*, a large cushion like a spherical segment, which, touching that of the opposite side, causes the air to whistle through the canal in its course to the mouth, and occasions the flute-like voice of some of these animals, as the weeper (*s. apella*) and the capuchin (*s. capucina*). In the howler (*s. seniculus*), so remarkable for its morning and evening yelling, though the larynx is similar in general characters to that of the common *sapajou*, in having the two rounded cushions before the ventricles, the hyoid bone is arched in the form of a spherical chamber, with a large quadrilateral aperture, and each ventricle opens into a membranous sac, lying between the *epiglottis* and the adjoining wing of the thyroid cartilage. The air, which passes between the vocal chords, is therefore partly impelled into this osseous and elastic cavity of the hyoid bone, and probably by its resonance in this situation gives the voice of these animals the deep-toned howl by which they are known in the American forests.

Voice of the howler ape,

Among the Zoophaga, in the dog the cuneiform cartilages are large, the arytenoid small, the vocal chords well marked, and the ventricles deep. In the feline tribe the anterior ligaments, though destitute of cuneiform cartilages, are thick, and separated from the back of the epiglottis by a broad, deep furrow. The posterior ligaments, though neither free nor sharp-edged, are distinguished from the anterior by an appearance of greater firmness, more regular fibres, and by an intermediate furrow. The approximation of the anterior ligaments towards the *glottis* forms a sonorous vault, in which the air may be forcibly vibrated by the posterior. In the bear the cuneiform cartilages assume the shape of styles, and their posterior extremity forms a distinct eminence, not above, but without the arytenoid cartilages, while the ventricles are merely deep fissures.

The kangaroo has neither cuneiform cartilage, anterior ligament, nor ventricle; and it may even be said to be void of vocal chord, while the margins of the *glottis* are much separated in the middle. This arrangement appears to indicate that the animal is almost destitute of voice. In the opossum, in which there is merely a small inferior ligament susceptible of tension, voice is limited to a whistling sound.

In the Solidungula, in which the cuneiform cartilages are completely concealed by the mucous membrane, there is neither superior ligament nor proper ventricle; but an aperture in the lateral wall of the laryngeal membrane, above the vocal chord, leads into a large, oblong, sinuous cavity, situate between this membrane and the thyroid cartilage, and covered chiefly by the thyro-arytenoid muscles, by which it may be compressed; and above the anterior commissure of the vocal chords, or below the base of the *epiglottis*, is an aperture on the mesial plane, leading into a cavity below the vault formed by the anterior margin of the thyroid cartilage. This cavity, which may be named the infrathyroid, is superficial in the horse, and its aperture is large; while in the ass, with a small, round aperture, the cavity is large, capacious, and globular in every direction, and allows the latter animal to make his voice re-echo in the singularly harsh sound denominated the *bray*. Conversely, though the lateral cavities are equally large in both animals, the apertures in those of the ass are small, round, and situate nearer the *epiglottis* than the vocal chord, while those of the horse are large, oblong, and situate immediately above the vocal chord on each side. On the latter peculiarity appears to depend the neigh of the horse.

of the ass, and horse.

In the Cetacea we recognise neither vocal chords nor *glottis*, that is to say, an aperture variable in size ac-

cording to the will of the animal; but the superior part of the *trachea*, which represents the larynx, forms a hollow pyramid or funnel, rising into the posterior part of the nostrils, in which only it opens, while on the sides is left a passage for the food. This pyramidal funnel is formed by an elongated triangular cartilage, corresponding to the *epiglottis*, attached by membrane to the arytenoid cartilages, which also take the shape of scalene triangles, with the small side connected to the cricoid cartilage. Strictly speaking, therefore, the CETACEA have no larynx, and probably no vocal organ; and the superior part of the *trachea*, with the nostrils, serves merely to admit the atmospheric air for the purposes of respiration.

BIRDS are distinguished by possessing not only a *glottis* or laryngeal aperture similar to that of the MAMMALIA at the upper end of the *trachea*, but a second, denominated the inferior *glottis* or *larynx*, at the lower end, near its bifurcation. The former, which is composed of four cartilages, or six, according as the cricoid consists of one or three pieces, on the middle of the posterior part of which is a small round bone, articulated with two oblong longitudinal bones, parallel, and forming between them in the posterior wall of the windpipe a longitudinal slit, susceptible of approximation by means of muscles, is intended merely to regulate the admission of air into the windpipe, or its expulsion from that tube, and to close more or less accurately its superior orifice.

Inferior or modulating larynx of birds.

The inferior larynx consists of a membrane projecting from each side of the inferior aperture of the *trachea*. This aperture is divided into two, occasionally by an osseous anterior-posterior middle bar, occasionally by the angle at which the two bronchial tubes unite. Since the first bronchial arc has the same curvature as the last tracheal ring, the second and third, which are arcs of larger circles, are less convex without, but more prominent within, than the former. Over this prominence the tracheo-bronchial membrane forms a fold, which, half closing on each side the inferior tracheal aperture, forms a plate susceptible of vibrating by the motion of the air, and producing sound. This apparatus, which constitutes what is named the *inferior larynx*, or rather *glottis*, is of two kinds, one void of proper muscles, the other provided with muscles.

In the former kind of larynx the state of the glottis is altered only by those muscles which depress and elevate the trachea. The depressors are two pairs, the sterno-tracheal and the glosso-tracheal, the latter attached to the bifurcated bone and *trachea*. There are no proper elevators; but the windpipe is raised by the mylo-hyoid muscle through the ligaments which connect the hyoid bone to the superior larynx. In the quiescent or relaxed state, and while the trachea is depressed, the bronchial rings approximate, and the second and third even gliding below the first, the *glottis* may be elongated. When the trachea is elevated by these pairs of muscles, the *bronchi* are at the same time dragged upwards, and the second and third arcs are separated from the first; and while the external prominence of the glottidal membrane diminishes in length, its tension is augmented. These forms of larynx without proper muscles may yet be subdivided into two sorts, as they have or have not lateral pouches, membranous or osseous. These are observed in the male duck (*anas*) and the merganser (*mergus*), but never in the female; and to this perhaps the harsh and deep tone of the voice of the male bird is to be ascribed. The larynx without muscles and without pouch is observed in all the gallinaceous order without exception.

The forms of larynx provided with proper muscles may be distinguished into three subdivisions.

The first, which has only one proper muscle on each side, is observed in the whole of the falcon *genus*, e. g. the eagle, hawk, falcon, buzzard, sparrow-hawk, and goss-hawk; in the owl *genus* and the majority of the waders and swimmers, as the heron, bustard, woodcock, lapwing, rail, coot, gull, cormorant, and some of the passerine birds. In these birds, in which the motions of the lower larynx are necessarily limited, the voice is not variable or extensive in its notes.

The second form of *larynx* has three pair of proper muscles, a *constrictor* of the *glottis*, an auxiliary constrictor, and a *laxator* or opener of the glottis. This kind of larynx is observed in the whole of the parrot *genus* and psittacoid birds generally, as the toucan, macaw, calao, &c.

In the third kind of musculo-membranous *larynx* there are no fewer than five pair of muscles, the longitudinal *levator* of the demiannular cartilages, the posterior *levator* of the same cartilages, the small *levator*, the oblique *levator*, and the transverse *levator*. This quinque-muscular larynx is found not only in all the birds properly named whistlers or warblers, as the nightingale, hedge-sparrow, blackbird, thrush, goldfinch, lark, linnet, canary, chaffinch, &c., but in others whose tones are more monotonous, as the swallow, sparrow, stork, crossbill, &c., and even in some the tones of which are harsh and positively disagreeable, *e. g.* the jay, magpie, crow, raven, &c.

The differences remarked in the notes of these three divisions of birds with the quinque-muscular larynx depend not so much on anatomical peculiarities as on the *timbre* of their larynx, and on the mobility of the *trachea* in relation to the larynx, and on the tracheal membrane having dilatations and contractions.

On the whole, the inferior larynx of birds is to be regarded in three lights: 1*st*, As the reed of a wind-instrument, like a hautboy or clarionet, in which the notes vary as the lower glottis varies in its position to the windpipe; 2*d*, as an instrument susceptible of uttering different tones, according to the distance between the mouth-piece and vent, or as the windpipe is elongated or shortened; and, 3*d*, as an instrument capable of uttering different notes by varying the diameter of the mouth-piece, or as the superior *glottis* is widened or contracted.

The only bird in which the inferior larynx is wanting is the vulture.

The vocal organ of the REPTILES consists of the superior larynx only, analogous to that of the MAMMALIA. This is a cartilaginous apparatus, composed in general of five distinct pieces at least in the large individuals of the SAURIAL *genera*, as the crocodile and alligator, and forming a broad cavity behind, before a narrow slit, bounded by two vertical pillars. The *glottis*, however, is entirely membranous; and there are neither vocal chords nor ventricles. There are nevertheless two muscles, one for opening and another for shutting the *glottis*. When these act, and the air is made to vibrate against the anterior pillars, it gives a slight whistling sound only. In the iguana, tupinambis, lizard, tortoise, and serpent, the arrangement of parts is nearly the same; and these animals, therefore, can utter only slight hissing sounds. In the chameleon the pillars are furnished with a tense, vibrating membrane, a fleshy tubercle which contracts the *glottis*, and a membranous pouch opening below, between the lower laryngeal cartilage and the first tracheal ring. In the frog tribe, so remarkable for their croaking noise, the vocal chords are large and prominent. The males have also two membranous pouches, opening by a small aperture, not in the larynx, but deep in the lateral part of the mouth. When the frog croaks these pouches are inflated, and swell the skin on each side below the ear. Though these sacs are wanting in the female frog, and toad both male and female, as well as the tree-frog, there is beneath the throat a single pouch on the median plane.

CHAP. V.—COMPARATIVE NEUROLOGY.

A general view of the nervous systems in different classes of animals shows that the only common part is an azygous tubercle, situate at the anterior extremity of the spinal chord, connected by means of two lateral bundles or peduncles to the rest of the system. This mass, which corresponds to what is denominated the *cerebellum* in man, is connected in the vertebrated red-blooded animals with several pairs of tubercles, forming generally a larger mass than itself, and connected to the rest of the system by two longitudinal bundles or limbs, which mingle with and intersect those of the cerebellum. These anterior-superior tubercles, which constitute the brain proper, present numerous modifications in figure, disposition, and magnitude, and even in presence, in the different orders of the animal world.

In the vertebrated animals the brain or central part of the nervous system consists of the vertebral or funicular portion, named the *spinal chord*, and the cranial or cephalic portion, properly denominated the brain.

Spinal chord.

The funicular portion has the shape of a *cylinder* flattened on its superior or dorsal and inferior or sternal surfaces. It consists of two similar chordiform productions, united on the mesial plane, and marked at the line of junction by linear longitudinal furrows, of which the superior is most deep and distinct. This, however, which was observed by Blasius in several animals, is denied by Bellingeri, who asserts, from various observations, that though in some parts the superior furrow penetrates more deeply than the inferior, in the general course of the chord the latter is the deepest. (*De Medulla Spinali Annotationes Anatomico-Physiologicæ.* Auctore C. F. Bellingeri, Aug. Taurinorum, 1823.) This discordance appears to depend on the circumstance that the sternal or inferior furrow is in truth deeper and more distinct in man, the monkey tribe, and a few MAMMALIA, than the dorsal; whereas in most others, as the coati, raccoon, horse, &c. the dorsal furrow is of the same depth as the sternal; and in the mole, murine, and leporine *genera*, it is deeper and more distinct than the sternal. In BIRDS and the cartilaginous FISHES the sternal furrow is deepest; in Reptiles the dorsal and sternal are nearly equally deep; and in the osseous FISHES the dorsal is the deepest. On each side of the chord, also, there is a slight longitudinal depression commonly called the lateral (*sulcus lateralis*).

The breadth and thickness of the spinal chord vary in different regions. The lower cervical portion is in general the broadest and thickest; at the upper dorsal region it is somewhat more slender, becoming thicker again at the lower dorsal region; and after again becoming more slender in the lumbar region, it is expanded into a filamentous brush-like termination of different lengths in different classes, and even in different orders. These enlargements at the superior dorsal and lumbar regions are believed by Serres to correspond with the origins of the thoracic and pelvic extremities; and each swelling he represents to predominate over the other, as the animal habitually employs the one or the other kind of members. It is remarkable in illustration of this principle, that in the CETACEA, which are void of pelvic extremities, the lumbar enlargement is wanting; and in the amphibious MAMMALIA, the pelvic extremities of which are feeble, this enlargement is also inconsiderable.

The spinal or funicular brain consists of white cerebral matter on the surface and gray matter in the centre, the former being most abundant, unless in the sacral region, where both are nearly equal in quantity, or the gray rather predominates. In the MAMMALIA the gray matter is in greater proportion to the white than in the other three classes, in which the white matter progressively augments.

The sternal and dorsal longitudinal lines indicate the original formation of the chord in two lateral portions, with an intermediate cavity denominated the spinal canal. This exists only during the formation of the chord in the human fœtus, in some of the MAMMALIA when adult, and in the other three classes. Its disappearance in the human fœtus, and in that of various MAMMALIA, is represented by Serres to depend on the progressive deposition of gray cerebral matter on the inner or central surfaces of the component pillars of the chord. Though obliterated in man, in whom the gray matter is abundant, it is not hermetically sealed in the monkey tribe, in which some traces of it are left. In the AMPHIBIA and CETACEA it is larger than in the monkey tribe; its diameter augments in the CARNIVORA, feline, canine, and ursine, in which the gray matter is thinner than in the former; and in the RODENTIA it is said to be largest of all among the MAMMALIA. Lastly, in the birds, reptiles, and fishes generally, in which the gray matter is scanty and the white predominates, the spinal canal is large and distinct.

The lateral regions of the spinal chord are connected with a double series of nerves by means of two rows of nervous filaments, an anterior and posterior, separated by a longitudinal membrane of fine white tissue, with a serrated or festooned border. This membrane, which is named the denticulate, is the same in the MAMMALIA and BIRDS. That these nerves do not issue from the spinal chord, must be inferred not only from the phenomena attending the original developement of the nervous system, but especially from what is observed of their comparative size, and that of the chord in the inferior classes. In that of fishes especially, while the chord is small and slender, and by no means fills the vertebral canal, it is remarkable that the nerves which supply the voluntary muscles are exceedingly large. Thus, in many both of the cartilaginous and osseous divisions, as the sturgeon, dog-fish, ray, wolf-fish, cod, &c. the nerves which supply the pectoral fins are large, broad chords, two or three of which seem to contain more substance than the whole spinal chord itself.

Bulb of the chord.

The chord is expanded at its cephalic end into a thick eminence denominated the spinal bulb, the surface of which presents three pairs of eminences. These eminences are developed in various degrees in the different classes and orders. In some of the MAMMALIA the anterior pyramids or pyramidal bodies are more distinct than in man, for instance the ape tribe, the CETACEA, CARNIVORA, Ruminants, and RODENTIA. They are small in most Birds, all the Reptiles, and the Cartilaginous FISHES. In the osseous division they assume the appearance of two parallel chords at the base of the brain. The olivary bodies, less prominent in the ape than in man, are still less so in the CETACEA, and progressively through the AMPHIBIA, CARNIVORA, RUMINANTIA, RODENTIA, and INSECTIVORA, and the other three great classes of vertebrated animals. Conversely, the restiform bodies or posterior pyramidal eminences, from man through the ape tribe, the CETACEA, AMPHIBIA, to the Ruminants, CARNIVORA, and RODENTIA, increase in size.

Though the brain of the MAMMALIA presents the same parts, and is arranged nearly in the same order, as that of man, it varies in its proportions to the rest of the body; in its proportions to the *cerebellum* and spinal bulb; in general figure; in the presence, absence, and number of convolutions; in the configuration of its central surface; in the communication of its central with its external surface; and in the manner of its connections with the cerebral nerves. As it is impossible in this sketch to examine all

these circumstances fully, we shall confine our attention to the notice of a few only.

It is not easy to ascertain the proportion of the mass of the brain to that of the rest of the body Excluding as much as possible the ordinary sources of fallacy, in small animals the brain is proportionally larger; yet in this respect man is surpassed only by a small number of animals, habitually lean, and with little muscle, as bats, small birds, &c. While the proportion of brain in man to that of the whole person varies from a 22d to a 35th part, that of the monkey tribe varies from a 22d to a 42d part; and in the baboon it is only the 104th part of the body. Among the MAMMALIA, the RODENTIA have in general the largest proportion of brain, and the PACHYDERMATA the smallest; and while the hare has a brain about the 300th part of the size of the body, that of the elephant, the most sagacious of animals, is about the 500th part the size of his body. It is also remarkable, that while the brain of the horse is only a 400th part of the size of his body, that of the ass amounts to a 254th part. The Reptile brain becomes excessively small, that of the turtle being rather more than the 5000th part the size of his body; and in some of the Fishes, not all, it appears to attain the maximum of decreasing proportion, that of the tunny being so small as the 37,000th part of his body, while the brain of the carp is so large as to approach the proportion of the elephant. It may be doubted whether, under such circumstances, any precise conclusions can be drawn from results so variable and so little to be expected.

The proportional weight of the brain to that of the *cerebellum* is, excepting in the case of one species of ape, the *saimiri*, greater in man than in any other animal. The ox is equal to man in this respect, and the dog approaches him. The animals most remote are the RODENTIA, as the beaver, rat, and mouse, &c.

The convolutions, which are so numerous and so deep in man, diminish both in number and size in the QUADRUMANA and CARNIVORA, and are nearly obliterated in the RODENTIA. In the UNGULATED animals, however, and especially in the Ruminants and the horse, the convolutions are numerous; and even in the dolphin among the CETACEA, they are numerous and deep. In all the MAMMALIA the *cerebellum* is foliated.

On the whole, the peculiar character of the brain of man and the ape family consists in the existence of the posterior lobe and digital cavity. The brain of the ZOOPHAGA is remarkable for the small size of the *nates* or anterior pair of the bigeminous eminences in proportion to the *testes* or posterior pair. In the RODENTIA the organ is distinguished for the large size of the *nates*, and the want or superficial nature of the convolutions. In the UNGULATED division of animals, *i. e.* PACHYDERMATA, RUMINANTIA, and SOLIDUNGULA, the brain is remarkable for the large size of the *nates* combined with the number and depth of the convolutions; while that of the CETACEA is remarkable for its height and breadth, and the want of olfactory nerves. It is further to be observed as a general distinction between herbivorous and carnivorous or zoophagous animals, that in the former the *nates* are larger than the *testes*, whereas in the latter the *testes* are largest. Lastly, Man and the QUADRUMANA are the only animals which possess genuine olfactory nerves. In the other quadrupeds they are represented by the mammillary processes of the ancients; and in the CETACEA they have not yet been unequivocally demonstrated.

The brain of BIRDS is at once recognised by consisting of six distinct tubercles, two representing the cerebral hemispheres, two representing the optic eminences, one the cerebellum, and one the bulb of the chord. The hemispheres are void of convolutions, but the cerebellum is marked by transverse parallel striæ corresponding to the *laminæ* of the mammiferous brain. There is neither middle band (*corpus callosum*), vault, nor *septum*. The ceiling or vault of the aqueduct or passage from the third to the fourth ventricle is not, as in the MAMMALIA, surmounted by the bigeminous eminences, but is merely a thin plate corresponding to the valve. Each optic eminence contains a cavity communicating with the others by the Sylvian aqueduct. The anterior eminences (*corpora striata*) are not striated with alternate white and gray matter, as in the MAMMALIA. Between the anterior and the optic eminences are four rounded tubercles, best seen in the ostrich, which are to be regarded as entirely heterologous to the structure of the mammiferous brain, and connecting the cerebral structure of BIRDS with that of Reptiles and Fishes, in which also these tubercles are observed.

The Reptile brain is smooth and unconvoluted. The optic eminences, which are situate behind the hemispheres, are uncovered, and contain a ventricle communicating with the third. At the extremities of the latter are the anterior and posterior commissures, but there is neither soft commissure nor bigeminous eminences. The hemisphere presents an anterior eminence, which, however, in the brain of Birds is unstriated. The cerebral valve is, like that of BIRDS, unsurmounted by bigeminous eminences.

In the class of FISHES the structure becomes still more simple. The tubercles of which the brain consists are placed in a row; and their increase in number only demonstrates the decomposition of the organ, and its resolution into simple integrant parts. The two representing the hemispheres are ovoidal, unconvoluted, and contain a ventricle, in which is seen the eminence analogous to the striated bodies. The optic eminences, situate beneath the hemispheres, though small, contain each a cavity, as in the two oviparous classes already noticed. Lastly, there are in several *genera*, under the common vault of the hemispheres, occasionally two, occasionally four tubercles, variable in shape and proportions, but which would be analogous to the bigeminous eminences, were they not, like those already mentioned in BIRDS, situate before and above the optic chambers. In the cartilaginous fishes, in which these tubercles are not observed, the anterior or striated eminences are obliterated. The *cerebellum* does not cover the fourth ventricle.

Behind the *cerebellum* are two tubercles, which in the ray give origin to the fifth pair, and are very distinct in the pike, trout, salmon, and perch. These tubercles are peculiar to this class.

The cavities in the interior of the optic eminences in Birds, Reptiles, and Fishes, are observed in the fœtal brain of the MAMMALIA during its early growth.

It is almost superfluous to mention, that, in the two warm-blooded classes, Mammalia and Birds, the brain, with its investments, fills completely the cranial and vertebral cavities. In the Reptiles, however, in which the brain does not approach the cranial walls, we remark the first departure from this arrangement; and in the Fishes it is so completely violated that the brain and chord occupy but a small proportion of the cranio-vertebral cavity; and between the former and the osseous walls there is a quantity of fine but very loose filamentous tissue, containing in its cells a large quantity of pellucid fluid. Though this arrangement gives this the appearance of a white jelly-like substance, it is not gelatinous, as is generally represented, but merely a pellucid fluid, sometimes pale straw-coloured, occasionally with a reddish tint, contained in numerous communicating cavities of a tissue which appears to represent the arachnoid of the warm-blooded animals.

Comparative Anatomy.

The *pia mater* in the reptiles and fishes is reduced to a filamento-vascular web, accompanying the blood-vessels.

The *dura mater* undergoes some peculiar modifications in different orders. In the duckbill a bony plate is contained between the *laminæ* of the falx; and the same structure is found in the porpoise, perhaps in the other CETACEA. An osseous *tentorium* with a quadrangular aperture is found in the coaïta and marten, and the feline and ursine families; and an osseous partition consisting of three parts is found in the dog, horse, Cape ant-eater (*orycteropus*), the wombat, and the seal. The bony *tentorium* is also found in the woodcock and others of the feathered class. In the red but cold-blooded animals the *dura mater* forms neither falciform nor tentorial process.

On the nerves or ramified chords of the nervous system a few words must suffice. In fishes the tenth or pneumogastric consists not of a common trunk, but of three orders of filaments, the first and largest of which are distributed to the gills, and correspond to the pulmonary nerves of the MAMMALIA; the second, slender, are distributed to the muscles of the tongue and the surface of the *œsophagus;* and the third terminate in a large nerve which traverses the body longitudinally immediately beneath the lateral line. The phrenic nerve is wanting in birds, reptiles, and fishes.

In the MOLLUSCA the nervous system consists of a number of whitish cerebral masses distributed in different parts of the body, with one or two more conspicuous than the rest, and supposed therefore to represent the brain, placed transversely over the œsophagus, which it encompasses with a nervous collar.

In the ARTICULATA the nervous system consists of two long chords extending along the belly, and expanded at various intervals into gangliform knots or enlargements. The first of these, which is situate on the œsophagus, rarely exceeds the others in size. Among the ZOOPHYTES hitherto examined the nervous system assumes either a radiated or an arborescent form.

PART II.

COMPARATIVE ANATOMY OF THE ENTROPHIC ORGANS.

CHAP. I. THE LIMITROPHIC ORGANS.—SECT. I. THE ORGANS OF DIGESTION.—§ 1. THE TEETH.

Though genuine teeth are found in three classes of animals only, viz. the MAMMALIA, the REPTILES, and the FISHES, yet all the orders of these classes are not provided with teeth. Thus, among the first class, the ant-eater tribe, the pangolin, the *echidna* and *ornithorhyncus*, and the whales—among the second the *cheloniads*—and among the third the sturgeon—are altogether destitute of these organs. In all the invertebrated classes, the jaws, when present, are provided with notches varying in number. The *echinodermata* alone have genuine teeth, inserted in a mechanical apparatus very different from ordinary jaws.

Though in general structure the teeth of the lower animals resemble those of man, in some respects they differ considerably. These varieties consist either in some change or modification of the constituent parts of the teeth, or in the addition of some other substance to those parts.

The first variety to be noticed is of the former description.

Bone of tooth.

Though in the QUADRUMANA and ZOOPHAGA the bony matter of the teeth is quite similar to that of man, in other orders this substance appears in the form of a very hard, compact, and more regularly fibrous substance than bone, and to which the name of ivory (*ebur*) is applied. It is chiefly in the canine or tearing teeth that this substance is found to represent the bony pillar of the teeth; and it is principally among the PACHYDERMATA, and some of the AMPHIBIA and CETACEA, that this change is observed.

Ivory of different animals.

The ivory of the elephant is the most tender, and that which most rapidly becomes yellow on exposure to air. It is readily distinguished from the ivory of other animals by the curve lines which radiate from the centre to the circumference of the tooth in various directions, and which form by intersection regular curvilinear lozenges.

The ivory of the hippopotamus is greatly harder and whiter, and is on that account preferably employed for the preparation of artificial teeth. A transverse section of this substance shows *striæ* extremely delicate and regular. In this animal, also, not only the canine but the incisor teeth consist of this substance. The tusks of the Ethiopian boar (*sus Æthiopicus*) consist of ivory similar to that of the hippopotamus. In those of the ordinary boar, though no *striæ* are recognised, there is sometimes a mixture of brown substance disposed in layers. The ivory of the teeth of the morse, though void of *striæ*, is compact and susceptible of polish nearly as brilliant as that of the hippopotamus; and its character is, that the central pillar of the tooth consists of minute round grains, indiscriminately aggregated, like pebbles in puddingstone. The axis or pillar of the molar teeth of this animal, which are without internal cavity, consists of similar minute grains. The ivory of the dugong is homogeneous and without *striæ*. That of the teeth of the white whale or cachalot resembles the bone of human teeth in its satin-like appearance. The ivory of the tusk of the narwal is very compact and homogeneous in appearance.

The most singular structure of teeth among quadrupeds is observed in those of the Cape ant-eater (*orycteropus*). The teeth of this animal, which have the appearance of two cylinders conjoined, consist of an infinite number of minute straight parallel tubes, so that their transverse section resembles that of a rush. As these tubes are closed only at the triturating surface, it is there only that the tissue of the tooth is compact; and when the enamel is worn, the upper orifices of these tubes begin to be exposed. There is, therefore, no general cavity in the interior of the tooth. These teeth are also void of root. A similar tubular structure is observed in the two molar teeth of the *ornithorhyncus*, and in the teeth of some fishes.

Enamel.

The enamel (*lamella vitrea, cortex striatus*) presents peculiarities in the lower animals, as well as the bone of the tooth.

While the enamel of the human tooth is confined to the crown, in several of the lower animals, as the morse, it envelopes the tooth all round; and in the molar teeth of this animal, which, indeed, are void of cavity, it is thicker under the root than at the crown. A similar arrangement is observed in the old or adult teeth of the cachalot, which, when their cavity is obliterated by the full deposition of osseous substance, are also covered with enamel below.

The texture or constitution of the enamel is best seen in the grinders of the elephant. The section of a tooth in the germ exhibits fibres similar to those of asbestos or fine velvet. The fracture of the enamel is more distinctly fibrous than that of the bone, and the fibres are everywhere perpendicular, or nearly so, to the surface of

Comparative Anatomy.

the tooth. The hardness of this substance may be inferred from the fact that it strikes fire with steel. These component fibres, however, are not always rectilineal. Most frequently they describe curves with the convexity of incurvation towards the crown and the concavity towards the root. This arrangement at least is observed in the ruminants. The distinction between the enamel and bony matter is recognised by a gray line, and another whiter which belongs to the latter substance.

The enamel varies chiefly in thickness in different animals. The tusks which project from the mouth are generally observed to be less white, less hard, and more similar to bone or ivory than the other teeth; and on this account, probably, the existence of enamel has been denied in the tusks of the elephant. It is nevertheless certain that the external layer of these tusks presents radiating fibres, though it is by no means so hard, or possesses the same grain, as the enamel of the other teeth. Enamel is more apparent, though thinner, in the tusks of the morse, dugong, and boar; and it is quite as distinct in those of the hippopotamus as in the other teeth of that animal. Lastly, the enamel of the teeth of the cachalot, which is very thick, shows in its section only *striæ* parallel to the surface of the osseous substance.

Teeth may be distinguished according to the mode in which their component tissues are arranged into three sorts. 1*st*, When the enamel invests the axis all round, and does not penetrate the latter, the tooth is said to be *simple* (*dens simplex*). Such is the character of the human teeth, and those of the QUADRUMANA and ZOOPHAGA, and several other animals, and all the reptiles.

Simple teeth.

2*d*, When the enamel is folded as it were round the bony part, but without inclosing it, so that the latter forms a continuous band several times folded on itself, and sections of the tooth in every direction divide repeatedly the component substances, the tooth is said to be compound or complex (*dens multiplex vel compositus*). A good example of this structure is seen in the grinders of the elephant.

Compound teeth.

3*d*, When the base or root of the tooth is simple, and the folds of the enamel and bone penetrate only to a certain depth, they are said to be semicompound. Examples of this modification of arrangement are seen in the grinders of the ruminating animals.

Semicompound teeth.

In the compound, and part of the semicompound teeth, the enamel is covered by a third substance; and as the latter is arranged, especially in the former sort, so as to leave intervals between it and the next layer of enamel, this substance serves to fill all these intervals, and consolidates the component lobes of the tooth even before their osseous parts are united below. This substance, which is denominated by Cuvier *cement*, by Tenon *cortex osseus*, and by Blake *crusta petrosa*, though less firm than either bone or enamel, is dissolved by acids more slowly than the former, and sooner becomes black in the fire. In the teeth of the elephant and *cabiai* it forms half their mass at least. In most *genera* it presents no apparent organization, and resembles a sort of crystalline tartar incrusted on the tooth. In the cabiai, however, it presents numerous pores very regularly arranged. Tenon was of opinion that it arose from ossification of the membrane which enveloped the tooth; blake ascribed it to deposition from the opposite surface of the enamel membrane; but Cuvier ascertained that it is deposited by the same membrane and the same surface as the enamel. This accurate observer found, on inspecting the germs of the teeth of the elephant, that when the internal membrane of the dental capsule has deposited the enamel, it undergoes a change of structure, and becomes thick, spongy, opaque, and reddish, to furnish the cement, which is then deposited, not in regular crystalline fibres, but in random drops.

The cement or *crusta petrosa*.

The teeth of the Reptiles consist of hard, compact, osseous matter, invested by a thin covering of enamel, and without cement.

Teeth of fishes.

The teeth of Fishes vary much in structure. They are either simple or compound. The simple teeth are those which consist of bone invested by enamel. They may be distinguished into two species, according to their mode of attachment. The first are the simple teeth, which are not implanted in *alveoli*, but merely attached to the gum, or fixed by articulation to the jaw, as those of the shark tribe; the second are simple teeth growing in alveolar cavities, as is observed in the majority of fishes, the pike, dory, &c. The simple teeth attached to the gum are chiefly distinguished by their fibres intersecting in the manner of the cancellated tissue of bones, and being therefore at first light, porous, and spongy, and becoming afterwards uniformly hard and compact like ivory.

The compound teeth, which consist of an infinite number of minute tubes mutually aggregated and invested by a common covering of enamel, form plates of different sizes, adhering to the bones of the jaws or palate by an intermediate membrane only. In some they affect the disposition of the quincunx; in others they occupy the whole breadth of the upper jaw at least, as in the ray as seen on the small scale, and in the same manner in larger fishes; others are in straight transverse bars; others assume the shape of a circular segment, or the figure in heraldry denominated the chevron.

In the wolf-fish the jaws are provided with eminences composed of fibres or tubes proceeding from the base to the circumference, and which are connected to the jaw by a substance more spongy than the rest of the bone.

Mechanical detrition of the teeth.

After their first formation the teeth retain nearly their original shape in the ZOOPHAGA, man, and the QUADRUMANA. In the two latter only their crowns begin to be worn, rendering the incisor and canine less pointed by the use of food partly vegetable; but in the zoophagous tribes they undergo no detrition whatever. In the herbivorous animals, however, the crown begins to undergo detrition more or less rapidly; and in no long time the superior layer of enamel is entirely worn off, and the surface of the tooth exposes the succession of bone or ivory, enamel, and cement. These substances are well seen in the teeth of the RODENTIA, for instance the hare; those of the PACHYDERMATA, as the elephant; the Ruminants, as the stag, sheep, and ox; and the SOLIDUNGULA, as the horse. In all these animals the enamel, which is hardest, forms prominent lines or ridges; while the bone and cement are indicated by depressions.

This detrition, which is purely mechanical, might proceed to such an extent in the herbivorous quadrupeds as to destroy the whole of the crown of the tooth, and leave the process of mastication to be performed by the jaws only. It appears to be chiefly to obviate this inconvenience that the dentition of the elephant, the Ethiopian boar, and perhaps all the PACHYDERMATA, is conducted in a successive manner through a series of six or eight sets of teeth at least. In the former animal, in which this process has been best observed, and was ably explained many years ago by Mr John Corse Scott (*Phil. Trans.* 1799), each half-jaw, whatever it contains, exhibits at one time only one complete grinder and part of another behind it, the prominent parts of which are placed obliquely to the horizon, forming an inclined plane, so that the anterior parts are worn before the posterior. The anterior complete one, which is employed in mastication, undergoes progressive detrition till its anterior portion is worn down to the level of the jaw. In this state the fangs of the anterior part of the tooth begin to diminish, rendering the tooth narrow before; while the crown of the poste-

Successive dentition of the elephant.

Comparative Anatomy.

rior begins to be worn, and undergoing the same detrition, the posterior fangs also begin to give way. While this process, however, is advancing, the posterior tooth, of which only the anterior part was appearing above the gum, gradually rises, with its crown forming a plane inclined from before backwards, similar to that of the anterior grinder. When this posterior tooth has been raised sufficiently to allow its anterior margin to be used in mastication, the residue of the anterior tooth drops out altogether, and the posterior one continues to rise and advance rapidly, until it is completed, when it is found to be much larger than the previous tooth, and to consist of a greater number of plates of ivory and enamel (*denticuli*). In no long time this new tooth, which undergoes the same process of detrition, is succeeded by another one, the anterior margin of which rises first behind the posterior one of its predecessor, and which passes through the same stages of growth, detrition, and shedding. This process is repeated at least seven or eight times, and each succeeding tooth is larger, and contains a greater number of ivory and enamel plates than its predecessor. The elephant has thus 7 or 8 grinders in each half-jaw, or 28 or 32 grinders respectively; yet there are never more than one tooth and part of another, or at most two, that is, eight teeth in the upper and lower jaws, at the same time. Though the disappearance of the fangs of the anterior tooth is ascribed to absorption—which indeed is a good general name—yet the true reason is the fact that the maxillary or dental vessels of the elephant are unable to sustain more than one tooth in each half-jaw at once; and that since these vessels gradually transfer their blood to the new tooth, while those of the old one shrink and are obliterated, as the new tooth grows the old one is actually dehematised or atrophied. The order in which the teeth of the elephant succeed each other is nearly the following. The first or milk grinder, composed of 4 eburneo-vitreous plates (*denticuli*), cuts the gum eight or ten days after birth, is well formed in six weeks, and completely out in three months. The second, which consists of 8 or 9 plates, is completely exposed at the age of two years; the third, consisting of 12 or 13 plates, at six years. The fourth to the eighth grinder consist of plates varying in number from 15 to 23; but the period at which these teeth appear has not yet been determined. This process has been shown to have taken place also in the gigantic fossil animal named the *mastodon*.

A similar process of displacement and renovation takes place in the poison-teeth of serpents, and in the teeth of the shark, *diodon*, and *tetraodon* tribes. In the wolf-fish (*anarrhicas lupus*) the teeth are shed along with the spongy membrane in which they are contained, exactly as the horns of the stag.

Dentition of the horse.

In the horse, in which the process of dentition has been carefully observed, it is usefully employed to determine the age of the animal. The milk incisors appear at the end of 15 days; the four middle ones, or the *nippers*, are shed at 30 months; the four following ones at 42 months; and the four external, or the corner teeth, at 54 months. The permanent corner teeth do not grow so quickly as the other incisors; and by these especially the age of the horse is determined. At first they scarcely rise above the jaw. Their middle then presents a hollow filled with blackish tartar, the margins of which are worn down as the tooth rises from the gum, and is rubbed against the corresponding one; and it diminishes progressively from 54 months to 8 years, when it is altogether obliterated. The hollow of the other incisors is obliterated at a later period than that of the corner ones; and the age of the animal is then estimated from the length of the incisors, which continue to increase.

The first two molar teeth appear in each jaw and on each side about the 8th day, the next at the 20th, and the complementary or small anterior grinder about the 5th or 6th month. The first posterior molar appears about the 11th month, and the second in the 20th. At the 30th or 32d month the first two milk grinders are shed, the third in the 3d year; and about the 5th or 6th year the last posterior grinder appears. The milk grinders are longer from before backwards than the permanent ones, which are themselves contracted in this direction, as they are pressed by the posterior grinders; from which it results that the dental crowns of young horses are oblong, while those of the old are quadrangular.

In the MAMMALIA the teeth are always implanted in the jaw-bones, and never, as in other animals, in the tongue, palate, &c. The only exception to this rule is the *echidna*.

Arrangement of the teeth.

The three kinds of teeth, incisor, tearing, and grinder, are found together only in Man, the QUADRUMANA, the ZOOPHAGA, the PACHYDERMATA except the elephant and two-horned rhinoceros, in the hornless Ruminants, and in the SOLIDUNGULA; but, of all these animals, in man only are the three forms of teeth arranged in an uninterrupted series, and in such a manner that those of the lower jaw are applied to those of the upper. In one other animal only, now extinct, the *anoplotherium*, is this continuity of arrangement observed.

In the QUADRUMANA and ZOOPHAGA, and all those in which the canine are larger than the other teeth, there is a gap on each side of the jaw to receive the canine of the opposite one. In the ursine genus there is a large empty space behind each canine tooth. In the hedgehog, shrew, phalanger, and tarsier, in which the canine are shorter than the other teeth, a space is left between them and those opposite. In the maki tribe, proper bat, colugo, and camel, there is a large interval between the upper incisors. Lastly, the Ruminants want the incisors of the upper jaw, and the morse those of the lower.

Some animals provided with the three classes of teeth lose the incisors at a certain age; for instance several of the bat tribe, and the Ethiopian hog. Other Mammalia have only two sorts of teeth, for instance incisors and grinders, separated by an interval without canine, as the wombat and all the RODENTIA, in which there are only 2 incisors in each jaw; the kangaroo, which has two below and 6 or 8 above; and the cavy or *hyrax* genus, which have 2 above and 4 below. The elephant has grinders and two tusks planted in the superior intermaxillary bone, but no inferior incisors or canine teeth.

Animals may possess grinders and canine teeth without incisors, as the sloth tribe and the dugong. The grinders, which are most essential, are most rarely wanting; and when others are deficient these are present, as in the armadillo tribe, the *orycteropus*, the *ornithorhyncus*, two-horned rhinoceros, and lamantin. The jaws of the dolphin are provided with uniform conical teeth all round, while the cachalot or white whale has them in the lower jaw only. In the narwal there are only two long spiral tusks implanted in the intermaxillary bone, and of these one is often wanting.

Absence of the teeth.

Lastly, teeth are entirely wanting in the ant-eater tribe, pangolin, and *echidna*, which are therefore arranged among the EDENTATA. In the whale the teeth are represented by plates of the laminated, fibrous, bluish substance distinguished by the name of *whale-bone*.

§ 2. ORGANS OF INSALIVATION.

Under this head ought to be noticed the modification which the salivary glands undergo in the lower animals. Our limited space, however, obliges us to proceed immediately to notice the peculiarities of the other divisions of the alimentary canal.

§ 3. Œsophagus, Stomach, and Intestinal Tube.

Œsophagus.

The muscular tissue of the œsophagus consists, in most of the Mammalia, of spiral fibres twisted in two opposite directions, the external from before backwards, the internal from behind forwards. This arrangement, which was first observed in the Ruminantia, was supposed to explain the process of rumination. This opinion, however, is refuted by the fact that the arrangement is not confined to this order, but is very general among the zoophagous and other animals which do not ruminate. In the kangaroo the direction of these fibres is, as in man, transverse in the internal layer, and longitudinal in the external.

The œsophageal mucous membrane is covered by epidermis, which extends to the cardiac opening of the stomach in man, the Quadrumana, and all the Zoophaga. This membrane, as well as the mucous, is thrown, by the action of the muscular tunic, into longitudinal folds, which are effaced only when the œsophagus is distended. In the tiger, lion, and lynx, there are large transverse valvular folds, and smaller ones in the civet and couguar—an arrangement connected probably with the carnivorous habit.

Stomach.

The stomachs of the lower animals vary considerably in shape, in the insertion of the œsophagus, in the disposition of their muscular tunics, and in the simplicity or complication of their cavities. These characters it is impossible in such a sketch as the present to consider in detail; and we shall confine our attention to those peculiarities which are most striking in the digestive organs of the animal world.

Simple stomach.

The stomachs of the Mammalia may be distinguished into the simple and compound. Those of man, the Quadrumana, zoophagous and most of the herbivorous tribes, belong to the former order. This simple form of stomach, however, may be generally distinguished into two parts, a cardiac and a pyloric, more or less separated from its other by a central transverse contraction of its annular muscular fibres. This is particularly seen in the horse, man, murine family, and many other animals which occasionally feed both on animal and vegetable matter. In the human stomach this contraction is represented in Plate XXXVI. fig. 4. In the porcupine, however, there are three pouches. This contraction depends on a strong annular band of muscular fibres at this part of the organ. In the pure carnivorous animals, however, as the feline family, the annular fibres, which are very thick, are nearly equally so from the cardiac to the pyloric end.

The compound stomachs, or those which contain more cavities than one, are found in the sloths, and the ruminant and cetaceous animals chiefly.

Bilocular stomach.

In the first tribe the stomach of the *Unau*, or two-toed sloth, is two-fold. The first cavity is large and globular, but tapering behind into a conical appendage, separated by a semilunar fold; while a large cul de sac on the left of the *cardia* opens into a canal which proceeds at first backwards, and then turning to the right, enters the second cavity by a narrow aperture. The second, which is small, tubular, and folded under the former from left to right, is distinguished by a semilunar fold into two halves, the first of which opens into a small cul de sac on the right side of the first cavity. The inner membrane of both cavities is smooth, and without *villi*. A similar arrangement is found in the *Ai*, or three-toed sloth, with this exception, that the appendage of the second gastric cavity is divided into three compartments by two longitudinal bands. This canal seems analogous to the arrangement of the ruminating stomachs, in so far as it may allow the alimentary matters to pass occasionally from the œsophagus directly into the second stomach.

The stomach of the *hyrax*, ashkoko, or Cape cavy, also consists of two pouches, separated by a middle partition, in which there is an aperture for mutual communication. In the hippopotamus the cardia communicates with three pouches, two of which only are cognizable without, and with a long tubular bowel, the interior of which is divided across by several valvular folds.

In the kangaroo the stomach receives the œsophagus near its left extremity, which is small and bifid (Plate XXXV. fig. 8); and forming a larger cavity on the right, passes upwards, making a turn, and crosses to the left before the œsophagus, makes another turn, and again crosses the mesial plane to the right, where it terminates in a tapering cavity at the pylorus. In this course it presents internally a longitudinal band (L, L, L), extending all round to near the pyloric end, and crossed by valvular membranous folds, which divide the cavity into cells not unlike those of the colon, especially in the horse. The mucous epidermis is continued from the œsophagus over the space marked *c*, *c*.

Quadrilocular stomach of the ruminants.

The stomach of the Ruminants consists of four distinct but communicating cavities. The first, denominated the Paunch (*κοιλια*, *rumen*, *penula*, *ingluvies*; *la panse*, *l'herbier*, *la double*), is a large bag occupying the left side of the abdomen chiefly, marked externally by two saccular appendages, and separated within into four parts. (Plate XXXV. fig. 1, A, A, A, A.) Its inner surface, upon which the epidermis is continued, is occupied by flat *papillæ*. By a pretty wide aperture (B, B), with rounded margins, this communicates with the second cavity named the Kingshood (*κεκρυφαλος*, *reticulum*, *le bonnet*), which is distinguished by the rhomboidal and polygonal cells, into which its inner membrane is moulded. An aperture at the further end of this (C) leads into the third or smallest cavity, termed the Maniplies (*εχινος*, *omasum*, *le feuillet*), from the numerous concentric crescentic folds formed by its inner membrane (fig. 2, *c* and P). These folds amount to about 40 in the sheep and 100 in the ox. The smallest of them, between the aperture from the second into the third cavity, are puckered or collected towards their further end by a transverse membranous fold, which acts as a valve to the aperture between this and the fourth cavity. This one, generally named the Red (*ηνυστρον*, *abomasum*, *la caillette*), is of an elongated pyriform shape, slightly incurvated on itself (fig. 2, D), and is marked internally by longitudinal folds (P) incurvated according to the curvature of the cavity itself, and terminating near the pyloric end in *rugæ* or irregular duplicatures (R). This is the structure of the gastric cavities in the ox.

In the camel, dromedary, and lama, the stomach is equally complicated, though the structure is a little different. In the first of these animals, which may be taken as an example of the others, the Paunch or first cavity is a large bag, divided into two compartments on the posterior part, by a strong band passing from the right side of the cardiac orifice longitudinally downwards (L, L, fig. 3), and forming one border of a groove leading to the orifice of the second. From the left margin of this band proceed eight muscular bands, nearly at right angles, and intersecting with others, form cellular cavities on the left side of the paunch (N); while on the right side there are similar cells, though smaller, and wholly unconnected with the longitudinal band. From the left margin of the cardia, in like manner, proceeds a broad muscular band (M, fig. 3) to the aperture (B) of the Paunch into the Kingshood, after which it takes another direction (M, fig. 4) towards the Maniplies or third cavity, within the orifice of which it terminates (C, fig. 4) The Red or fourth chamber is much the same as that of the bullock (D, P, R, fig. 5), and the only peculiarity is, that after terminating in (Π) the pylorus, it opens in a small cavity (O) which leads into the duodenum (Δ).

Comparative Anatomy.

Water-cells of the camel.

From this description, for the particulars of which we are indebted to the accurate account of Sir E. Home, it results that the stomach of the camel differs from that of the ox and other horned ruminants chiefly in the possession of the quadrilateral cells in the second stomach. Into these the water is conveyed by the animal when drinking, and in these it remains. By the action of the muscular band (M), the aperture between the Paunch and Kingshood is opened, and the water is directed into it so as to fill its cells. When these are filled the surplus runs off into those of the first stomach, where at least those on the left side of the long band may be regarded as part of the general cellular structure. These cells are represented of a large size in fig. 5, in which they appear like oblongs with rounded corners. They are always larger on the left side of the band, in the Paunch, than those in the second stomach.

Both in the bullock and in the camel, and in all the Ruminants, the first and second stomachs only are covered by mucous *epidermis*.

Quadrilocular stomach of the Cetacea.

In the Cetaceous animals similar complication of the gastric cavities is observed. In the bottle-nose porpoise, which may be taken as an example, the œsophagus, which is large and capacious, terminates in a spheroidal or ovoidal flask-like bag (fig. 6, A, A) with an aperture a little below the cardiac, consisting of rose-like annular folds, and leading into a second cavity. This, which corresponds to the ruminant kingshood, is nearly spherical in shape (fig. 7, B), and presents valvular folds more circular than in the ruminants, and intersected by others so as to give it the honeycomb appearance characteristic of this cavity. From this another aperture leads into the smallest cavity of the three (C, fig. 7); and thence into the fourth, which is long, cylindrical, and slightly incurvated. The third cavity is remarkable for presenting in its inner membrane numerous apertures of mucous glands.

Crop of birds.

Birds are distinguished by possessing a stomach consisting of three cavities. The first is the crop, which may be regarded as a mere expansion of the œsophagus, and confined chiefly to land birds. It is filled not only with food, but with small stones; and its chief purpose seems, by mechanical comminution, to supply the place of the teeth in dividing the granular aliment, and bruising or killing the animals swallowed. It is found chiefly in the granivorous birds. It is wanting in the ostrich, in the piscivorous birds, and most of the GRALLÆ.

Glandular crop.

The second is the glandular crop or subsidiary stomach (*ventriculus succenturiatus, bulbus glandulosus*), a membrano-glandular sac, which may be also regarded as an œsophageal dilatation. It is larger when the crop is wanting; and though, when conjoined with it, it is always very glandular, and may be therefore regarded as a chemical solvent of alimentary substances, it appears to supply the want of the crop, which is certainly chiefly a mechanical apparatus. The glandular crop or subsidiary stomach is remarkable for the number and size of the glandular bodies contained between its mucous and muscular tunics. These glands, though variable in shape, are generally conical; and some consist of several glands conjoined in one common peduncle (Plate XXXVI. fig. 3). All of them are hollow, and secrete a fluid which is discharged by one or more minute apertures, and which is of essential importance in the solution of the food. In some instances, as in the American ostrich (fig. 2), they are few in number, and occupy only a small part of the posterior wall of the œsophagus.

Gizzard.

The gizzard or proper stomach of birds may be considered as a horny mucous membrane, somewhat cartilaginous, continuous with that of the œsophagus, and covered by two strong thick muscles, the fibres of which converge to a point. (Plate XXXVI. fig. 1.) In the carnivorous and piscivorous *genera* of birds, especially those in which the crop is wanting, the gizzard loses its muscular character, and is converted into a membranous pouch.

Reptile stomach.

The stomach of REPTILES does not present those dilatations observed in BIRDS; and when it changes its diameter or capacity, it is only progressively and insensibly. Its general diameter, nevertheless, is proportionally larger than in the two classes already noticed. Most generally without *cul de sac*, its shape is spheroidal, more or less oblong; its membranous walls are thin and transparent; its muscular layer almost imperceptible; the cellular identified with the mucous tissue; the situation of the *cardia* indeterminate; and the *pylorus*, without valve, is distinguished by a simple tapering contraction of the gastric walls, and the appearance of the structure proper to the intestines.

In this class of animals, further, digestion appears to be less regulated by fixed principles than in the other two. It is evidently not confined exclusively to the stomach. The œsophagus of the turtle is provided with numerous large, firm, pointed processes, which in all probability contribute to the mechanical division of the food, so much the more requisite as the CHELONIAD REPTILES are toothless. Except in the crocodile, the SAURIAL Reptiles are destitute of large arch or proper cardiac cavity. In the OPHIDIAL or Serpentine Reptiles the stomach has the figure merely of a dilated sac between the œsophagus and intestines, and presents no curvature. It is probably in connection with this modification of structure that we find animals remain for days in the œsophagus of serpents; and this tube appears to be to a certain extent capable of digesting aliment as much as the stomach. The best mark of distinction in such circumstances is the cessation of *epidermis*.

Stomach of fishes

In no class of animals does the stomach vary more in shape, structure, and situation, than in FISHES; and perhaps the general character of the alimentary canal in this class is most justly given by representing it as deviating from those attributes of regularity which we find in the higher classes. While in the MAMMALIA and BIRDS it is always distinguished by its spheroidal or pyriform enlargement between two tapering extremities, and by being much more dilated than any other part of the alimentary canal, in the Reptile class it begins to part with this character; and it loses it altogether in the Fishes. In most of the finny tribes it is often not more capacious than the œsophagus; and it is distinguished from this tube only by the villous character of its internal membrane. In general, also, the situation of this pyriform dilated sac is transversely across the body in the Mammiferous class. In the feathered tribes this character also is slightly set aside, and partly from the alteration in shape, partly from that of position, the stomach occupies less of the transverse diameter than of the longitudinal extent of the body. Among the Reptiles this character, though still retained in the CHELONIAD, and even in the SAURIAL, is gradually enfeebled in the OPHIDIAL; and in the FISHES it may be said to be entirely obliterated, since the organ occupies much more longitudinal extent than transverse width of the body.

The first character of the alimentary tube of fishes is the width or capacity combined with shortness of the œsophagus. The latter character is manifestly associated with the absence of lungs and consequent want of chest; so that between the throat and abdominal cavity, the interval, which corresponds only to the space occupied by the heart, is extremely abridged. The œsophagus consists, as in the other classes, of a mucous membrane surrounded by a muscular tunic; but the mucous membrane is distinguished by the firmness and whiteness of its corion, which in some *genera* approaches to the consistence of horn or cartilage, and by the presence of conical *papillæ*, sometimes of great hardness, and which appear to

Comparative Anatomy.

act mechanically on the food. It is almost superfluous to notice the facility which the large capacity of this tube affords fishes for swallowing their prey. Most of them are voracious in the extreme; and it is not uncommon to find the stomach and œsophagus crammed to the throat.

The figure and position of the stomach of Fishes are so variable, that it is difficult to give a character of general application. Though in many *genera*, especially of the JUGULARES, it consists of a cylindrical sac with a slight dilatation immediately below the *cardia*, in others it is oblong ovoidal, as the ray and shark tribe; and in others, as the sole, dory, and flat fishes generally, it is orbicular. In the sturgeon it consists of a cylindrical tube incurvated twice on itself. In none is there more than one *cul de sac*, the depth of which varies as the part corresponding to the *pylorus* is more or less remote from the *fundus*. When the limits of the stomach are indistinct, the situation of the cardia is equally so. In the lamprey (*petromyzon*) and pen-fish (*syngnathus pelagicus*) the whole tube is of a uniform size from the mouth to the anus; and much the same may be said of the carp genus. The genera in which it forms a distinct dilatation or cul de sac are chiefly the following; the eel (*murœna anguilla*), conger (*m. conger*), the bullhead *genus* (*cottus*), the *scorpœna horrida*, *labrus genus*, perch, cuckoo gurnard, mackerel, herring, salmon, *mormyrus genus*, mullet, and *silurus Bagre*. In the anableps the dilatation disappears; and in the *chœtodon ciliaris* and some others it is a large sac incurvated in an arch-like bend.

The intestinal canal in most of the Mammalia is very similar to that of man; and the chief differences of different orders and genera are found in the difference of longitudinal extent either of the whole intestinal tube or the comparative lengths of its several parts.

Comparative length of the intestine to the body.

From the time of Grew to that of Cuvier, and most modern anatomists, it has been a point of some importance to determine the length of the intestinal tube in relation to that of the body. This comparative length, which is greatest in the MAMMALIA, diminishes successively in the BIRDS, REPTILES, and FISHES. It has been occasionally stated by different anatomists, that the intestinal tube is longer, *cæteris paribus*, in granivorous than in carnivorous animals, and conversely. When we come, however, to compare the different lengths of this tube in the several tribes, we find that this statement demands modification. In the ape family its length varies from 5 to 8 times that of the body; in several of the *lemur* tribe from 4 to 6 times, the smaller length being in this case compensated by the size of the *cæcum*; and in others of the lemur tribe, *e. g.* the *lori*, the intestine is only three times the length of the body. Among the CHIROPTERA there are two examples of very great contrast in this respect. While the intestine of the *noctula* or great bat (*vespertilio noctula*, Lin.) is the shortest of all the MAMMALIA, and scarcely does more than exceed the length of the animal's body, that of the roussette (*pteropus*) or East India bat, which lives chiefly on vegetable matter, is at least 7 times longer than its body. A similar instance of the meeting of extremes is found in the Marsupial order, in which the marmoset and cayopollin have intestines only $2\frac{1}{2}$ times longer than the body, while that of the phalanger is more than 11 times longer. In the plantigrade or ursine family, which occasionally live on vegetable matters, the proportional length approaches to that of the ape.

In the carnivorous animals the intestine, though generally short, varies from 3 times to 8 times the length of the body. The former is the proportion in the lion, wild cat, ocelot, couguar, and weasel; and the latter in the hyena. Some of them also vary among themselves. Thus the intestine of the wild cat is greatly less than that of he domestic animal. The proportion is very great among the RODENTIA, in several of which it is 8, 10, 12, or 16 times longer, as in the agouti, than the body of the animal. Among the murine tribe, however, it undergoes a diminution. Among the EDENTATA, again, especially the sloth tribe, it diminishes very much, being only about $3\frac{1}{2}$ times longer than the body in the *Ai* and *Unau*. This brevity is so much the more extraordinary that these animals are void of cæcum, and live on vegetable matters; but, in all probability, the duplicature of the gastric cavities in some degree compensates this deficiency.

The intestinal tube attains its greatest proportional length in the Ruminant animals, being at least 11 times longer than the body, as in the goat, and 28 times longer in the ram. This immense length is supposed to compensate the absence of dilatation in the large intestines, and the small size of the cæcum. In the SOLIDUNGULA, again, which are remarkable for the large size of the cæcum, the length of the intestine diminishes much, being 8 times longer than the body in the zebra, 9 times in the ass, and 10 times in the horse.

Lastly, it is a singular circumstance, that in different species of the same genus the comparative length varies much. We have already noticed the difference between the length of the intestine in the wild and in the domestic cat. The wild and tame boar is a similar instance of the same, the intestine being only 9 times longer than the body in the former, and so much as $13\frac{1}{2}$ times in the latter. It is possible that such differences may depend on the different habits of the animal in his wild and domestic condition. This explanation, however, is totally inadequate to account for the difference in the comparative length of the intestinal tube in the Asiatic and African elephant, being 10 times longer than the body in the former species, and only 7 times in the latter. The same may be observed of two animals very closely allied, if not of the same *genus*, the *echidna* and *ornithorhyncus*. The intestine of the former animal is 7 times longer than his body, while that of the latter is only 5 times.

In BIRDS generally the intestine is shortest among those genera which prey on animals and fish; it varies from twice to five times the length of the body. In the gallinaceous and passerine birds, which live on grains, it is always longer and more capacious than in those which live on animal substances. In the cassowary, which is granivorous with a short intestine, the intestine is divided by contractions into distinct pouches, to compensate for the brevity of the tube. It must be remarked, nevertheless, that in several birds which prey on fishes, the intestinal tube is proportionally longer than in those which feed only on grain; and the proportional length is not diminished in birds living indiscriminately on animal and vegetable aliment.

The intestinal tube of the Reptiles is still shorter than that of Birds, and often it does not exceed twice the length of the body. It is longest in the CHELONIAD, and shortest in the RANINE and SERPENT tribe. In the tadpole, however, a singular peculiarity is observed. The intestinal tube of the tadpole of a frog is nearly ten times longer than the space between the muzzle and the vent (*anus*); whereas, after the animal has become a frog, the intestine is only twice as long as this space.

In the class of Fishes the intestinal tube is still shorter and more direct in its course to the vent or outlet. In a few which live chiefly on marine vegetables, for instance some of the *chætodon genus*. it is about six times longer than the body of the animal; and in a few of the carp *genus* (viz. *cyprinus capæta*) it amounts to ten or twelve times longer than the body. In others, however, of the same genus, for instance the *cyprinus mursa*, it is scarcely as long again, showing here once more an instance of the conjunction of extremes not easily explained.

Comparative Anatomy.

Distinction into *ileum* and *colon*.

In most vertebrated animals the intestinal tube may be distinguished by natural marks into two divisions, one extending between the pyloric end of the stomach to a part of the tube, where it becomes wider and more capacious; the other from this to the vent or outlet. In some instances, however, this distinction is very obscurely and imperfectly marked. In the MAMMALIA, in which the distinction is observed, it is indicated by one or more appendages, which, if large, are denominated *cæca*, and if slender and long, are termed *vermiform processes*. Man, the ourang, and the wombat (*phascolomys*), are the only animals which are possessed at once of *cæcum* and vermiform appendage. In the other genera of the ape tribe, in the maki of the *lemur*, in the colugo among the CHIROPTERA, the ichneumon, many of the carnivorous tribe, the opossum and kangaroo, the RODENTIA except the dormouse, the Cape ant-eater, the PACHYDERMATA except the hyrax, the Ruminants, SOLIDUNGULA, and AMPHIBIA, there is only a cæcum without vermiform process. The cæcum is wanting in the sloths, the bat tribe, the Ursine except the ichneumon, the marten, pine-marten, weasel, &c. the dormouse, and all the Cetaceous animals.

The presence of cæcum or vermiform process, however, is not necessary to distinguish the canal into two portions. The inner or mucous surface of the *ileum* is always villous and uniform; and the whole intestine, except its superior or pyloric portion, is convoluted in proportion to its length, and moves about freely in the abdominal cavity; whereas the colon is more or less fixed at different points, it is shorter and more capacious, and its inner membrane is merely mucous without long *villi*. A mark equally general is the semilunar duplicature of mucous membrane placed between the ileum and colon, and named the *ileo-colic* valve. In the sloth and armadillo tribes, which want cæcum and vermiform process, this and the slight difference of diameter are the only marks of distinction between the ileum and colon. In all the other MAMMALIA which are destitute of cæcum the whole tube is of the same calibre, occasionally diminished towards the vent; and the division into *ileum* and *colon* is no longer cognizable.

In all the MAMMALIA with one cæcum, it appears in the form of a production from the large intestine beyond the part at which it receives the *ileum;* and though variable in its diameter and structure, it bears a general resemblance to the colon in these respects. In herbivorous animals, and even in some that are omnivorous, as the ape and lemur tribes, it is generally large and puckered by tendinous bands. To this, however, an exception is observed in the Ruminants, in which the cæcum is moderate in size and unpuckered. It is small and unpuckered in the kangaroo-rat and wombat; while, conversely, in the colugo and brown phalanger, which are believed to be chiefly zoophagous, it is very large and puckered.

In the zoophagous animals generally both the *colon* and *cæcum* are of small calibre, little different from that of the *ileum;* and both the colon and cæcum are destitute of cells or compartments. In herbivorous and several omnivorous animals, on the contrary, the inner surface of the colon is divided by longitudinal and transverse bands into a number of cells or compartments. From this rule, however, there is an exception in the wombat, kangaroo, and the Ruminants. In the RODENTIA the colon is cellular at its commencement only.

In birds the canal is provided with two *cæca*, one on each side, not far from the vent. In the omnivorous and granivorous these *cæca* are generally long and capacious. While they are very large in the nocturnal predatory birds, they are either obliterated or wanting in the diurnal predatory birds, in the green woodpecker, the lark, and the cormorant. In the heron, bustard, and grebe, there is a single small one; in the cassowary two very slender; and in the merganser, diver, &c. they are short and thick.

In all birds the short bowel between the insertion of the *cæca* and the *cloaca* is a little wider and more capacious than those between the *pylorus* and the *cæca;* and this is the only circumstance which indicates in this class the distinction of the tube into *ileum* and *colon*.

In the reptiles the intestinal tube is generally void of *cæca* or appendage; and the only distinction consists in the one part of the tube, which is long and slender, being joined to another which is short and thick, and in the presence of a semilunar membranous fold at the point of insertion. In the *iguana* alone has a genuine *cæcum* been observed.

The distinction into small and large intestine, or *ileum* and *colon*, is still less obviously observed in the class of fishes. It sometimes happens that the difference of capacity is inverted, and that the calibre of the portion which terminates at the vent is actually smaller than that of the part connected with the stomach. This arrangement is observed in the ray, shark, sturgeon, and even the bichir; in the *syngnathus*, trunk-fish, and *balista*. In other instances the diameter is the same throughout; and the only distinction is derived from the anatomical characters of the inner membrane. In the lamprey, sea-devil, rough star-gazer, radiated sole, *holocentrus sago*, carp tribe, *mormyrus*, and mullet, it is impossible to distinguish the intestine into large and small.

Pyloric appendages of fishes.

FISHES resemble REPTILES in being destitute of *cæcum* at the junction of the small and large bowel. In many of them, however, there is attached to the intestine, somewhere below the *pylorus*, a variable number of small intestines terminating in blind ends, similar in size and structure to the intestine with which they communicate. These tubes, which have been not very happily named *pyloric* appendages (*appendices pyloricæ*), in so far as they are most frequently connected rather with the part of the bowel corresponding to the duodenum, vary in number from 2, 4, 6, or 8, to 80 or 180 in some genera, and even their number is not the same in different species of the same genus. Thus, while there are 6 in the smelt (*salmo eperlanus*), there are 68 in the *s. lacustris*, and 70 in the salmon (*s. salar*). In like manner, though there are 18 in the anchovy (*clupea encrasicolus*), there are 24 in the herring (*c. harengus*), and fourscore in the shad (*c. alosa*). In some, as the cod and pollach, they consist of several large trunks ramified into numerous small ones.

Peculiar form of the appendages.

These appendages, however, are wanting in the cartilaginous fishes with free *branchiæ*, in most of those with fixed *branchiæ*, in the APODES, and in several of the thoracic and abdominal order. In the sturgeon and some others they are represented by a series of communicating cavities inclosed in the intestinal membrane, which is covered by a cellulo-muscular tunic and peritoneum (Plate XXXVI. fig. 5), and which assumes the external appearance of a pancreas.

The spiral valve of fishes.

Among the cartilaginous fishes the brevity and directness of the intestinal tube is compensated by a peculiar disposition of the intestinal mucous membrane. This consists in part of the membrane projecting like a broad fold or process from the inner surface of the intestine, and winding round from the pyloric to the anal or lower extremity (fig. 7 and 8). This, which is denominated the spiral valve, may be easily understood from these figures, which represent the arrangement as it is observed in the shark. In the sturgeon, in which it is found in the last portion of intestine (fig. 6), its peculiarities have been described by the writer of this article in the *Wernerian Transactions*, vol. vi.

Rectum.

In all the MAMMALIA the intestinal tube terminates in a distinct bowel denominated the *rectum*, the mucous membrane of which is continuous with the skin at the

anus. This rule can scarcely be said to be violated in the case of the *echidna* and *ornithorhyncus*, in which there is an aperture at the lower part for the urine and the semen of the male and the *ova* of the female. These anomalous and singular animals form a transition to the mode in which the intestinal tube terminates in the three genuine oviparous classes. In BIRDS, REPTILES, and most of the cartilaginous FISHES, the intestinal tube terminates in an outlet common to it with the urinary organs, denominated generally the *cloaca*. In the sturgeon, however, it has been shown, in the paper already mentioned, that there is a distinct urinary outlet; and that consequently this animal cannot be said to have a *cloaca*. In the greater part of fishes, while there is one vent for the excrement, there is another common one for the urine, the *ova*, and the spawn.

Cloaca.

On the subject of the liver, spleen, and pancreas, it is impossible to enter with any interest in this sketch.

CHAP. II. SECT. I.—THE HEMATROPHIC ORGANS.

The Mammalia and Birds agree in having a heart consisting of two pairs of chambers, a venous auricle and ventricle, and an arterial auricle and ventricle. The Eustachian valve is often wanting in the Mammalia. It is wanting, for instance, in the lion, bear, and porcupine; while it is broad and muscular in the seal, and assumes a spiral direction along the upper walls of the right auricular sinus in the elephant.

It was at one time imagined that the aquatic MAMMALIA were distinguished from the terrestrial by the *foramen ovale* being open and forming a communication between the two auricles. This, however, is a mistake, at least in the adult animal; for neither in the otter, the seal, nor the porpoise or dolphin, did Cuvier find this aperture pervious; and it may be inferred, that when it is open, it is an anormal remain of the fetal structure. In the *ornithorhyncus*, also, according to Sir Everard Home, it is impervious. In the porcupine and elephant, in which there are two anterior *venæ cavæ*, the blood of the left anterior *cava*, which opens in the sinus near the aurico-ventricular aperture, is conveyed directly into the right ventricle.

The reptile heart, the first in the cold-blooded division, varies somewhat in the several tribes. In the first three, the CHELONIAD, SAURIAL, and OPHIDIAL, it consists of two auricles and one ventricle, divided in some instances into communicating chambers. In the Batrachoid family, on the contrary, it always consists of one auricle and one ventricle, the interior of which is unilocular or undivided. In several of the Turtle tribe, among the first family, the ventricle consists of a pulmonary chamber, in which the blood is more particularly directed to the pulmonary artery, and a general or aortic chamber, which is above, and from which the blood is conveyed into the aorta. In the crocodile the ventricle is divided into three chambers, communicating by several apertures. One is inferior and to the right, and communicates with the right auricle by a large aperture provided with two valves. On the left, and before, is the second chamber, receiving the orifice of the left descending aorta. Behind is an aperture leading into the smallest chamber of the three, situate at the middle of the base of the heart, and receiving the common trunk of the pulmonary arteries. The left chamber is above. In the OPHIDIAL or SERPENTINE family the ventricle is divided into two chambers, a superior and inferior, separated by an imperfect partition, which allows the two to communicate.

The heart of the finny tribes is as simple as that of the Ranine reptiles, which indeed constitutes the preparatory step in the descending scale of organic forms. It consists, as in these animals, of two chambers only, an auricle and ventricle. The former receives the blood from the body at large, and transmits it to the ventricle, which is almost in all cases unilocular. From this a single vessel conveys it, not to the body at large, but to the gills, from which it is again collected by several branchial veins.

Of the blood-vessels of the four vertebrated classes it is superfluous to speak in any detail.

The most remarkable circumstances are the minute subdivisions which in some classes the arteries undergo previous to final distribution. In the Ruminants, and several of the PACHYDERMATA, the branches of the carotid artery, instead of uniting by the communicating vessels, are subdivided into a great number of minute vessels, which form round the pituitary gland a communicating plexus, denominated by the ancients *Rete mirabile*.

In the slow lemur (*lemur tardigradus*) Sir A. Carlisle found the subclavian artery, after entering the axilla, divide into 23 arterial cylinders of equal size, and the iliac on the brim of the pelvis into at least 20 equal-sized tubes, which in both cases surrounded the principal artery, reduced to a small vessel, and, proceeding along the extremity, were distributed chiefly to the muscles. (*Phil. Trans.* 1800.) A similar arrangement, carried to a still greater extent, was found in the *Ai* or three-toed sloth, in which the axillary and iliac arteries were divided into about 60 or 65 cylindrical parallel tubes. In the slender lemur (*Lemur loris*) these vessels are subdivided into 4 or 5 only.

In Fishes in which the unilocular ventricle sends its blood to the gills only, the heart is pulmonary, and the arterial system is destitute of central impulsive organ. In the sturgeon, which is one of the best examples of the distribution of the arterial system in the finny tribes, the blood, which is distributed in the *branchiæ* by the large artery, is collected in numerous vessels, which may be regarded as analogous to the pulmonary veins of the warm-blooded classes, but which have thick *parietes* like arteries; and these uniting, form a large vessel, which is lodged in a cartilaginous canal formed by the continuous bodies of the *vertebræ*. This vessel is further void of compressive or elastic tunics, and the blood moves through it as through an immovable and inelastic tube. From its sides, however, a series of arterial vessels issue, which forthwith assume the usual characters of arterial tubes. In many other fishes the *parietes* of the large artery adhere in part to the semi-osseous canal in which it is lodged.

SECT. II.—THE ORGANS OF AERATING CIRCULATION.

The lungs of the MAMMALIA are in all essential points perfectly similar to those of the human subject.

The lungs of Birds differ chiefly in not presenting distinct lobules, in having the air-vessels larger and more distinct, in the branchial tubes not becoming quite so small, and in terminating not alone in the pulmonic vesicles, but in perforated parts of the surface of the lungs, which lead into large air-sacs, communicating with all parts of the body, and forming an accessory lung. In the ostrich, which may be taken as a general example, there are four of these cells or aerolabous sacs. The first, which is anterior, extends from the *apex* of the chest to the iliac bones, between the first ribs and heart above, and between the lower ribs and a cell which surrounds the intestines. It is divided into four chambers, the first two communicating with the lungs by large apertures, while the fourth opens in the iliac bones. Behind this large sac are two small ones, between the iliac bones and the peritoneal sac. Before it is another small one occupying the lateral regions of the *apex* of the chest, and communicating with sacs in the *axillæ* and neck. Besides these, the stomach, liver, heart, and intestines are surrounded by sacs. All of these communicate by saccular processes with the cavities of the bones. By this peculiar arrangement BIRDS possess the greatest extent of respiratory surface of all classes of animals.

Comparative Anatomy.

The lungs of Reptiles are distinguished by consisting of large sacs, subdivided by membranous partitions into polygonal cells, which again are subdivided by smaller slips into smaller cells. In these cells the bronchial tubes are not ramified, but divide abruptly in them at the surface of the lung. Some idea of this arrangement may be obtained from the lung of the ordinary land-tortoise (*Testudo Græca*, Plate XXXVII. fig. 1). The sacs or large cells are smaller and more numerous in the turtle (fig. 2); but the general disposition is much the same.

Temporary gills of the tadpole.

The young of the Batrachoid family, and several of the water-lizard tribe, are provided with fimbriated or ciliated processes attached to the neck, and which are in all respects similar to the gills of fishes. These gills disappear as the animal grows; and when it assumes the true ranine or reptile character, vesicular lungs like those of other reptiles, and which had continued in a hitherto latent and rudimental state, are developed, and the animal breathes as others of the same tribe.

A peculiar form of respiratory organ is found in the lamprey or seven eyes, and the two species of hag-fish, (*Myxine*, Lin.; *Gastrobranchus*, Bl.; and *Gastrobranchus Dombey*). The former has on each side seven apertures leading into cylindrical tubes, in which the branchiæ are contained. (Plate XXXVII. fig. 3.) In the two species of hag these tubes are dilated into ovoidal cavities, in which the water is received, and on the membrane of which the branchial vessels are distributed. In this respect, therefore, the hag-fish approaches to the mode of respiration among the cephalopodous MOLLUSCA, in which the *branchiæ* are inclosed in a cavity. Lastly, in the *Aphrodite aculeata*, which may be taken as an example of the respiration of worms, there is a series of tubes like *tracheæ* and *bronchi*, proceeding from the surface to the interior, and in which the water containing the air requisite for respiration is received. (Fig. 6.)

SECT. III.—SECRETORY ORGANS.

Urinary organs of the oviparous classes.

Under this head ought to be described the urinary organs of the four vertebrated classes. Those of the MAMMALIA agree in consisting of kidneys more or less lobulated, ureters or excretory tubes, a reservoir or urinary bladder, and a urethra opening on the same mucous surface with the organs of generation. In the three oviparous classes considerable changes are made. Though in Birds and Reptiles the glandular organs denominated kidneys are left in the shape of aggregated glands with the two excretory tubes, the bladder is withdrawn, and the ureters open in the *cloaca*. The only apparent exceptions are the ostrich and cassowary, in which the *cloaca* is so organized that it may serve as a bladder or temporary receptacle of the urinary secretion. In the Reptiles the presence of this organ is variable, being found in the CHELONIAD and BATRACHOID; and the iguana, tupinambis, chameleon, stellio, and dragon, among the SAURIAL tribe; but wanting in the crocodile, lizard, *agami*, gecko, and the whole OPHIDIAL tribe. In Fishes it is not less variable. While the ray and shark tribe are destitute of bladder, and the ureters terminate in a *cloaca*, this receptacle exists in the sea-devil, lump-fish, globe-fish, and others of the cartilaginous division.

Poison gland and fangs of serpents.

A peculiar secreting organ, deserving notice, is the poison gland of the poisonous serpents. It is a glandular body situate on each side above the upper jaw, behind and below the eyes, with a considerable cavity, which opens into a long excretory tube, lying along the outer surface of the upper jaw, and opening in the tubular tooth, represented at fig. 17 and 18; and which is movable in an articulation, and may be erected, as in fig. 18, or depressed, as in 16, at the will of the animal. The poisonous serpents are therefore distinguished from the innocuous by the presence of the erectile movable tubular fangs. Fig. 15 is the head of the innocuous, and 16 of the poisonous serpent.

PART III.—REPRODUCTIVE ORGANS.

Under this head we mention only the nipple-bag (*marsupium mammillare*), or secondary uterus of the Marsupial animals (Plate XXXVII. fig. 7); the nipples (fig. 8); and the manner in which the fœtal animal, in a very imperfect and embryal form, becomes attached by the mouth to the nipples (fig. 10). The *Marsupium*, therefore, ought to be regarded, not as a mere pouch in which the young may take refuge after they are grown, but as a subsidiary *uterus*, combining the character of the *Mammæ* of the other orders.

The MAMMALIA are peculiar in possessing a *uterus*. In the other classes this organ is withdrawn, and the ovary (fig. 11) and oviduct alone are left. In the ovo-viviparous animals, as the ovo-viviparous shark, the oviduct (fig. 12) resembles that of the common fowl. In the lower classes the ova are hatched out of the body entirely.

In the space assigned to this article, it was impossible to treat fully of a subject so extensive as the structure of the animal world; and while the author has arranged its divisions in such a manner as to show in what order it may be most easily and advantageously studied. he has introduced only those topics which are most indispensable, and most require illustration. For more complete details, therefore, he refers the reader to the following works.

1. *Leçons d'Anatomie Comparée* de G. Cuvier, Membre de l'Institut National, &c.; recueillies et publiées sous ses yeux par C. Duméril, chef des Travaux Anatomiques, &c. Cinq tomes. Paris, tome i. 1799;—tome v. 1805. 2. Blumenbach's *Manual of Comparative Anatomy;* with additional Notes by William Lawrence, Esq. F. R. S. Second edition, revised and augmented by William Coulson Lond. 1827, 8vo. The notes are derived chiefly from the work of Cuvier and the papers of Sir E. Home in the *Philosophical Transactions.* 3. Gore's Translation of *Carus's Introduction to the Comparative Anatomy of Animals.* Lond. 1827, 2 vols. 8vo. The arrangement of this work, in which the author examines the forms of organs as they ascend, from the lowest to the highest classes, diminishes its general interest. 4. *Lectures on Comparative Anatomy, in which are explained the Preparations in the Hunterian Museum.* By Sir Everard Home, Bart. Lond. 1823, 6 vols. 4to. This work consists of the papers read by the author at the Royal Society, and published in their Transactions. Though entitled, therefore, *Lectures on Comparative Anatomy*, it embraces a much more extensive field, and contains a great number of physiological and pathological papers. This renders it at once rather desultory and prolix. It contains, nevertheless, a great number of facts illustrative of peculiarities of structure in the animal world; and it is particularly valuable by the number of engravings with which it is embellished. It can scarcely be said to possess any arrangement whatever. 5. *Recherches sur les Ossemens Fossiles, où l'on rétablit les caractères de plusieurs animaux dont les Révolutions du Globe ont détruit les espèces.* Par M. le Bar. G. Cuvier, &c. Nouvelle édition. Tome i. 1822, Osteology of the Elephant, Hippopotamus; tome ii. partie i. 1822, Osteology of the Rhinoceros, Horse, Hog, Daman, and Tapir; tome iv. 1823, Osteology of the Deer and Ox, the Bear, Hyena, Lion, Glutton, Wolf, and Dog; tome v. partie i. 1823, Osteology of the Reptiles, the Ichthyosaurus and the Plesiosaurus; partie ii. 1823, RODENTIA, EDENTATA, MONOTREMA, AMPHIBIA, and CETACEA. Paris, 1824. These papers contain much accurate osteological description.

(D. C.)

Anatomy Act || Anaxagoras.

Anatomy Act, and Anatomical Schools. Notwithstanding the reputation to which a few British anatomists have attained within the last hundred years, before the passing of the *Anatomy Acts* of 1831 and 1832 the study of practical anatomy in Great Britain was all but proscribed by statute. Early, it is true, in the sixteenth century, by way of encouraging anatomical studies, it was ordained that "the bodies of four murderers should be delivered after execution to the corporation of *barber-surgeons* of London, for the purposes of dissection;" and at that time we were not much behind the rest of Europe in anatomical knowledge: but our legislation regarding the supply of bodies for the dissecting-room remained stationary, while the rest of the world was advancing, as became apparent by the fact, that until the middle of the last century our students were forced to seek anatomical knowledge in the various schools of Italy or of Holland. Yet our courts of law were in the habit of punishing medical men for professional ignorance, and our public boards of requiring anatomical skill in those who appeared before them for examination, while the laws prohibited the means of obtaining it at home; and it was even penal for any one to be in possession of a human body for anatomical purposes, except it were that of an executed murderer.

In defiance, however, of such strange discouragements, anatomy, especially in London and Edinburgh, made much progress, by the public winking at notorious transgressions of the law; but this anomalous state of things produced a class of offenders termed *body-snatchers*, whose revolting and, in some instances, atrociously criminal modes of supplying the dissecting-room were exposed in the parliamentary inquiry that preceded the Act now noticed.

By previous Acts of Parliament the criminal courts had been empowered to annex to the capital sentence on a murderer, that his body should be *publicly dissected*. But it was justly considered that thus the idea of great crime was connected with dissection, and the prejudices of all classes against anatomy greatly increased. Accordingly, in the second year of William IV., a parliamentary committee investigated the subject, and in the following year an act was passed that abolishes *dissection* as a part of any criminal sentence, legalizes schools of anatomy, and permits the possession of human bodies for the purpose of dissection, under judicious regulations, which are sufficient to prevent the revolting practices of the body-snatcher, and the still more atrocious crimes for which Bishop in London and Burke at Edinburgh were executed. Under this act the supply of bodies in our anatomical schools has been sufficient, without violating the sepulchres of the dead, or outraging the feelings of the living. The average supply of bodies to the London schools is estimated at 600 annually.—See *Report of House of Commons, of 22d April* 1829; *and Anatomy Bills of 5th May* 1829, *of 17th December* 1831, *and of 8th May* 1832.

ANAXAGORAS, an eminent philosopher of antiquity, was born at Clazomenæ (now *Kelisman*), in the first year of the 70th Olympiad, or 500 B.C. (*Apollodorus*). His family was rich and noble, but he early sacrificed the prospects of worldly ambition to his passion for philosophy. Leaving his patrimony to be cultivated and enjoyed by his relations, he gave himself up to the contemplation of nature, which he regarded as the true object of man's existence. "To philosophy," he afterwards said, "I owe my worldly ruin, and my soul's prosperity." Some writers call him the pupil of Anaximenes; but this statement, if taken literally, is irreconcileable with chronology. According to others, he enjoyed the instructions of his countryman Hermotimus, who, according to Aristotle, was the first to proclaim the doctrine of a supreme regulative intelligence. At the age of 20, or according to others, of more than 40, he went to Athens, at that time entering on the most brilliant period of its history, and there continued for 30 years. His philosophical teachings soon drew around him the best intellects of Athens, and he numbered among his pupils Pericles, Euripides, Archelaus, and probably also Socrates. Without interfering in the public affairs of the state, he contented himself with forming the minds of its rising youth in the principles of wisdom. But neither the elevation and disinterestedness of his character, nor the powerful friendship of Pericles, could ward off the shafts of persecution. The philosopher was accused, like Socrates in the next generation, of impiety (ἀσέβεια) and enmity to religion, in introducing new and dangerous opinions concerning the gods. He was charged, among other things, with teaching that the moon was but a mass of matter like the earth, and the sun (the bright Apollo) a fiery mass of inanimate substance. The philosopher was tried and condemned to die; but the eloquence of Pericles procured the commutation of the sentence into a fine and banishment. Anaxagoras retired to Lampsacus, where he continued to teach philosophy till his death in the 73d year of his age, B.C. 428. "It is not I," said he in his exile, "who have lost the Athenians, but the Athenians who have lost me." The day of his death was for several centuries commemorated by a yearly holiday, called the *Anaxagoreia*, in all the schools of Lampsacus.

Anaxagoras.

Opinions the most contradictory have been attributed to this philosopher. From the fragments that survive of his writings, and the statements of others regarding his opinions, it is impossible to obtain a systematic view of his doctrines. Diogenes Laertius, in his *Life of Anaxagoras*, has collected, with little care and judgment, details which were scattered through various writings. It appears that, in the midst of some extravagant conceptions, Anaxagoras held opinions which indicate a considerable acquaintance with the laws of nature. His idea of the heavens seems to have been that they were a solid vault, originally composed of stones elevated from the earth by the violent motion of the ambient ether, inflamed by its heat, and by the circular motion of the heavens fixed in their respective places. He considered the sun to be a fiery mass of stone *larger than the Peloponnesus*; and Xenophon introduces Socrates as refuting that doctrine, and delivering an unfavourable opinion concerning his other writings. The moon he believed to be *inhabited*, and to have its light reflected from the sun. Hence we find his disciple, Euripides, calling the moon not the *sister*, but the *daughter*, of the sun. From his perceiving that the rainbow is the effect of the reflection of the solar rays from a dark cloud, and that wind is produced by the rarefaction, and sound by the percussion of the air, he seems to have paid considerable attention to the phenomena of nature.

Our information is more correct concerning his opinions of the principles of nature and the origin of things. He imagined that in nature there are as many kinds of principles as there are species of compound bodies; and that the peculiar form of the primary particles of which any body is composed is the same with the quality of the compound body itself. For instance, he supposed that a piece of gold is composed of small particles which are themselves gold, and a bone of a great number of small bones: thus, according to Anaxagoras, bodies of every kind are generated from similar particles. The universe, according to him, consisted in the beginning of an infinite variety of these elementary principles (ὁμοιομέρη), which were afterwards mixed and arranged by the moving force of intelligence (νοῦς). "He was the first," says Diogenes Laertius, "who superadded mind to matter, opening his work in this pleasing and sublime language:—"All things were confused; then came mind and disposed them

in order." Aristotle, in like manner, says, that he taught that intelligence was "the cause of the world, and of all order; and that while all things else are compounded, this alone is pure and unmixed." Reason (λόγος) he held to be the regulative principle of the mind, as the *nous* is of the universe. The senses inform us regarding external phenomena; but this information, he held, required the correction of reason. The fragments of Anaxagoras have been collected by *Schaubach*, Leipsic, 1827, and again in a better edition by *Schorn*, Bonn, 1829.

ANAXARCHUS, a Grecian philosopher, who lived under Philip of Macedon and Alexander, was born in Abdera, and belonged to the sect generally known by the name of the Eleatic. He is said to have been instructed in his early studies by Diomenes of Smyrna, or Metrodorus of Chios. He had the honour to be a companion of Alexander; and a few anecdotes transmitted to posterity concerning him render it evident that he treated him with the usual freedom of a friend. He checked the vain-glory of Alexander, when, elated with pride, he aspired to the honours of divinity, by pointing to his wounded finger, saying, "See the blood of a mortal, not of a god." We are likewise told, that, on another occasion, while the king was indulging immoderately at a banquet, the philosopher repeated a verse from Euripides, reminding Alexander of his mortality. It is, however, to be regretted, that the fidelity of the philopher was wanting at the time when the mind of Alexander was tortured with remorse at having slain his friend Clitus; for it is reported that on that occasion he endeavoured to soothe the agitated mind of Alexander by saying, that "kings, like the gods, could do no wrong." It is said that Nicocreon, tyrant of Cyprus, commanded him to be pounded in a mortar, and that he endured this torture with incredible patience; but as the same fact is reported of Zeno the Eleatic, there is reason to suppose that it is fabulous; and it may be added, that this narrative is inconsistent with the general character of Anaxarchus, who, on account of his easy and peaceable life, received the appellation of "The Fortunate." Regarding his philosophical doctrines we have no information, save that he held the sovereign good to consist in perfect tranquillity of mind (ἀπάθεια).

ANAXILAUS of Larissa, a physician and Pythagorean philosopher, was banished from Rome by Augustus, B.C. 28, on the charge of practising the magic art. This accusation appears to have originated in his superior skill in natural philosophy, or what may be called "natural magic."—Euseb. *Chron. ad Olymp.* clxxxviii; St Iren. i. 13; Plin. xix. 4, xxv. 95, xxviii. 49, xxxii. 52, xxxv. 50.

ANAXIMANDER, a famous Greek philosopher, a friend or pupil of Thales, was born at Miletus in the 42d Olympiad, in the time of Polycrates, tyrant of Samos, 610 B.C., and died at the age of 63. He was the first who publicly taught philosophy, or wrote upon philosophical subjects, and carried his researches very far into nature. It is said that he discovered the obliquity of the zodiac, was the first who published a geographical table, invented the gnomon, and set up the first sun-dial in an open place at Lacedæmon. The primary essence he held to be infinite (ἄπειρον), all-embracing, and divine; that this infinite always preserved its unity, but that its parts underwent changes; that all things came from it; and that all returned into it. According to all appearance, he meant by this obscure and indeterminate principle the chaos of the other philosphers. He asserted that there is an infinity of worlds; that the stars are composed of air and fire, which are carried in their spheres, and that these spheres are gods; and that the earth is placed in the midst of the universe, as in a common centre. He added, that infinite worlds were the product of infinity, and that corruption proceeded from separation.

ANAXIMENES, an eminent Greek philosopher, born at Miletus; the friend, scholar, and successor of Anaximander. He diffused some degree of light upon the obscurity of his master's system. He made the first principle of things to consist in the air, which he considered as immense or infinite, and to which he ascribed a perpetual motion. He asserted that all things which proceeded from it were definite and circumscribed; and that this air, therefore, was God, since the divine power resided in it and agitated it. Coldness and moisture, heat and motion, rendered it visible, and gave it different forms, according to the different degrees of its condensation. All the elements thus proceed from heat and cold. The earth was, in his opinion, one continued flat surface.

ANAXIMENES, a Greek historian and rhetorician, was born at Lampsacus, a city of Mysia in Asia Minor, in the fourth century B.C. Some writers ascribe to him the Treatise on the Principles of Rhetoric, which bears the name of Aristotle; and it is reported that Philip of Macedon invited him to his court to instruct his son Alexander in that science. He attended Alexander in his expedition against Persia. The history of Philip, of Alexander, and likewise twelve books on the early history of Greece, were the productions of his pen, but only a very few fragments exist.

ANAZARBUS, or ANAZARBA, in *Ancient Geography*, a city of Cilicia, on the left bank of the Pyramus, eleven miles from Mopsuestia. Augustus changed its name to Cæsarea (ad Anazarbum), and on the division of Cilicia it became the metropolis of Cilicia Secunda. It suffered severely from earthquakes in the reigns of Justinian and Justin. Its site is supposed to be the present Anawasy or Naversa.

ANBAR, a town of Asia, in Arabian Irak, on the Euphrates. It was taken by Khaled, lieutenant of the khalif Omar, in the year 634, and rebuilt by the first khalif of the Abbassides. It is 35 miles west of Baghdad. Long. 43. 2. E. Lat. 33. 15. N. This is also the name of a fortified town in Independent Tartary, 20 miles north-east of Khiva.

ANBERTKEND, the Hindustanee name of a celebrated book of the Bramins, wherein the Indian philosophy and religion are contained. The word in its literal sense denotes *the cistern wherein is the water of life.* The Anbertkend is divided into 50 beths or discourses, each of which consists of 10 chapters. It has been translated from the original Indian into Arabic, under the title of *Morat al Maani*, q. d., *the marrow of intelligence.*

ANÇA, a small town of Portugal in the province of Douro, near Coimbra. It has extensive quarries of a fine bluish-white stone, which is exported in considerable quantities.

ANCASTER, a parish of Lincolnshire, once a Roman station, and considered by many antiquarians as the Causennæ of Antoninus. Area 2800 acres; pop. in 1851, 589.

ANCENIS, an arrondissement in the department of the Loire-Inferieure, in France. The extent is 305 square miles, or 195,436 acres. It is divided into five cantons, and these into 27 communes. Population in 1851, 48,102. The chief place, of the same name, contains 3661 inhabitants.

ANCESTORS, those from whom a person is descended in a direct line. The word is derived from the Latin *ancessor*, contracted from *antecessor*, goer before. Many nations have paid honours to their ancestors. It was properly the departed souls of their forefathers that the Romans worshipped under the denominations of *lares, lemures*, and *penates*, or *household gods.* Hence the ancient tombs were a kind of temples, or rather altars, whereon oblations were made by the kindred of the deceased.

ANCHISES, in *Fabulous History*, a Trojan prince, the son of Capys, and descended from Dardanus. He was honoured with the affections of the goddess Venus, who bore him a son named Æneas, the hero of the Æneid.

ANCHOR, in *Navigation*, from the Greek ἄγκυρα, which Vossius thinks is from ὄγκη, a *crook* or *hook*, an instrument of iron or other heavy material used for holding ships in any situation in which they may be required to lie, and preventing them from drifting by the winds or tides, by the currents of rivers, or any other cause. This is done by the anchor, after it is let down from the ship by means of the cable, fixing itself into the ground, and there holding the vessel fast. The anchor is thus obviously an implement of the first importance in navigation, and one on which too much attention cannot be bestowed in its manufacture and proper construction, seeing that on it depends entirely the safety of the vessel in storms. The invention of so necessary an instrument remounts, as may be supposed, to the remotest antiquity. The most ancient anchors consisted merely of large stones, baskets full of stones, sacks filled with sand, or logs of wood loaded with lead. Of this kind were the anchors of the ancient Greeks, which, according to Apollonius Rhodius and Stephen of Byzantium, were formed of stone; and Athenæus states that they were sometimes made of wood. These sorts of anchors retained the vessel merely by their inertia, and by the friction along the bottom. Iron was afterwards introduced for the construction of anchors, and also the grand improvement of forming them with teeth or flukes to fasten themselves into the bottom; whence the words ὀδόντες and *dentes* are frequently taken for anchors in the Greek and Latin poets. The invention of the teeth is ascribed by Pliny to the Tuscans; but Pausanias gives the merit to Midas, king of Phrygia. Originally there was only one fluke or tooth, whence anchors were called ἑτερόστομοι; but shortly afterwards the second was added, according to Pliny, by Eupalamus, or, according to Strabo, by Anacharsis, the Scythian philosopher. The anchors with two teeth were called ἀμφίβολοι or ἀμφίστομοι, and from ancient monuments appear to have been much the same with those used in our days, except that the stock is wanting in them all. Every ship had several anchors, the largest of which, corresponding to our bower or sheet anchor, was never used but in extreme danger, and was hence peculiarly termed ἱερά or *sacra;* whence the proverb *sacram anchoram solvere*, as flying to the last refuge.

Antiquity of anchors.

Weight of anchors of different sizes.

Anchors are now universally made of wrought iron, excepting in Spain and some parts of the South Sea, where they are made of copper. One essential quality in every anchor is a sufficient weight and angle of arm and fluke to fix itself in the bottom; and this has been determined by practice for different anchors, and for vessels of different sizes.

Large vessels have several anchors of different sizes, which are stowed in different parts of the vessel. These are distinguished by different names, viz., the *best bower* to the starboard; and the *small bower* to the port cathead, with the flukes on the bill-board; the *sheet-anchor*, on the after part of the fore-channels on the starboard side; and the *spare-anchor* on the port side. The above anchors are of the same size and weight. The two latter are only let go in cases of danger, when the vessel is riding in a heavy gale. In men-of-war they are always kept ready for letting go. The *stream-anchor* is of a much smaller size than the above, used only for riding in rivers or moderate streams. It is not generally above one-fourth or one-fifth of the weight of the others. Lastly, the *kedge-anchor* is still smaller, being only about one-half of the stream-anchor, and is only used when kedging in a river. Ships of the large class carry four large and three small anchors, and the smallest class, as brigs, cutters, and schooners, three or four.

The weight of anchors for different vessels is allowed by the tonnage. A pretty near rule for the principal anchor of ordinary-sized vessels is to allow for the cwts. in the anchor one-twentieth of the tonnage. Thus a vessel of 400 tons would require her principal anchor to be 20 cwt., or according to the following tables:—

MERCHANT VESSELS.

Tonnage. Tons.	Cable Chain. Inches.	Weight of Anchor. Cwt.
20	$\frac{9}{16}$	1
35	$\frac{11}{16}$	$1\frac{3}{4}$
50	$\frac{3}{4}$	$2\frac{3}{4}$
65	$\frac{13}{16}$	$3\frac{1}{2}$
70	...	$4\frac{1}{2}$
80	$\frac{7}{8}$	5
100	$\frac{15}{16}$	$5\frac{3}{4}$
130	1	7
160	1	8
190	$1\frac{1}{8}$	$9\frac{1}{2}$
220	$1\frac{1}{8}$	$10\frac{1}{2}$
250	$1\frac{3}{16}$	12
280	$1\frac{1}{4}$	14
320	...	$15\frac{1}{2}$
380	$1\frac{3}{8}$	$17\frac{1}{2}$
430	$1\frac{7}{16}$	20
480	$1\frac{1}{2}$	21
520	$1\frac{1}{2}$	25
720	$1\frac{11}{16}$	33

VESSELS OF WAR.

Guns.	Tonnage.	Cable Chain. Inches.	Weight of Anchor. Cwt.
20	500	$1\frac{3}{8}$	25
24	700	$1\frac{1}{2}$	29
28	750	$1\frac{1}{2}$	33

120	3000	$2\frac{1}{4}$	99 to 100

Form and dimensions of anchors.

Next to the weight, the form of the anchor, and the proportions of the different parts, are of great importance. The most general form, and that which has indeed been almost universally adopted all over the world, is that represented at Plate XXXVIII. fig. 1, and in section at Plate XXXIX. fig. 1, consisting of the two hooked arms for penetrating and fixing themselves into the soil; the long bar or shank for attaching the cable; and the stock, which is attached to the extremity of the shank, and serves to direct one of the points downwards into the soil. The weight of the anchor then causes the point to penetrate more or less according to the softness or hardness of the bottom; and the action of the vessel on the cable, instead of loosening the anchor, tends rather, by the hooked shape of the arms, to fix these deeper and firmer into the soil; so that the vessel is held quite fast, unless either the cable itself gives way, or any part of the anchor, or the anchor is dragged along owing to the looseness of the soil. The cable draws upwards by the extremity, and turns the whole round the point of the fluke. The one end of the shank is made square, to receive and hold the stock steadily in its place without turning. To keep the stock also from shifting along the shank, there are raised on it from the solid iron, or welded on it, two square tenon-like projections, called nuts. The length of the square of the shank is about one-sixth of the whole length of the shaft, and the thickness about one-twentieth. From the end of this square the shank increases in thickness, tapering towards the extremity, where the arms are attached: in all this part it is either made wholly round, or with a flat on opposite sides, or polygonal. The end next the stock is called the *small round*. The other extremity, where the arms and the shank unite, is called the *crown*, and the point of the angle between the arms and the shank the *throat*. Here the thickness of the shank is from $1\frac{1}{2}$ inch in small anchors, to 3 inches in large ones, greater than at the small round. A distance equal to that between the throat of one arm and its bill is marked on the shank from the place where it joins the arms, and is called the *trend*. Near the extremity of the square part of the shank is the hole for receiving the *shackle* for the cable, which is about half the thickness of the small round, and the diameter nearly equal to the length of the square. The shackle is lapped with cordage to prevent the cable from chafing. When hempen cables are used in her Majesty's service, one length of bower chain cable called a *ganger*, is bent to the spare anchor, and the hempen cable united with Admiral Elliott's shackle.

The *arms* make an angle of about 56° with the shank.

They are made either round or polygonal like the shank, about half their length. The remainder of the arm consists of three parts, the *blade*, the *palm*, and the *bill*, Plate XXXIX. fig. 1, and in another view at fig. 2. The blade is merely the continuation of the arm in a square form. The palm or fluke is a broad, flat, triangular plate, fixed on the inside of the blade, the use of which is, by exposing a broad surface, to take a firmer hold of the ground. The bill is the extremity of the arm, where it is tapered nearly to a point, for the purpose of penetrating more readily into the soil. In some cases the arm is made quite straight from the crown to the bill; in others, and particularly in small anchors, the interior half is made with the arch of a circle. The whole length of the arm is nearly half the length of the round part of the shank. It tapers slightly from the throat to the blade, where it is about the same thickness with the small round of the shank. The palm is about one-third of this in thickness, and the breadth of its base is nearly equal to its length.

The *stock* of the anchor, represented at fig. 3, is made of oak, consisting of two beams embracing the square, and firmly united by iron bolts and hoops. The length of the stock is rather greater than that of the shank, the thickness in the middle about one-twelfth of its length, and tapering to about the half of this at the extremities, the taper being all on the under surface next the arms, and the other quite straight. The taper is not quite regular. It commences at about half the breadth of the stock from the shank, and continues in one straight line to the extremity. The beams of the stock are hooped close together at the extremities, but gradually open towards the centre, that, in case of the wood shrinking, the hoops may be driven farther in, fig. 4. Of late years the stock has frequently been made of wrought iron, the same as the anchor; and this plan is now very generally followed in anchors up to sixty cwt. It has this advantage, that the stock can be at any time taken out and laid parallel with the anchor, which is very convenient for stowage. The iron stock, fig. 10, consists merely of a long round bar, about half the diameter of the anchor at the square. Instead of embracing the anchor, like the wood, it goes through a hole in the square, which is swelled out to receive it. It has a shoulder in the middle, which rests against the square, and a key driven through a hole in the stock on the other side keeps it fast. When the stock is to be taken out of its place, the key is driven out: the stock then slides through the hole in the shank, and by means of a bend at its extremity, it is laid parallel with the shank.

The operation of the anchor is easily understood. Being let down by means of the cable, the weight of the arms throws them downwards, and keeps the whole in a vertical position until it reaches the ground, where it lights upon the crown; and then falling over, the position of the stock at right angles to the arms, and its length and height, together with the weight of the cable, are sure to throw it with one of the arms pointed into the ground, if it does not take this situation of itself. This effect is aided by the anchor descending quickly—and hence it must be allowed to descend freely; for which purpose, in *throwing* or *casting* the anchor, the cable is arranged, one end being attached to the anchor and the cable bitted on deck, and the inner end removed below. Everything being prepared, the lashing of the anchor is cast off, and the men stand ready to let go; and when this word is given by the person in command, the fastenings are all cast off, and the anchor, falling into the sea, descends with rapidity. When the anchor, again, is to be removed from its situation and drawn up into the vessel, the operation is termed *weighing;* which requires often a very heavy purchase, particularly at starting. This is obtained by means of the windlass or capstan, round which the cable is wound, and a number of hands applied to work it. With cables which are too large to be wound round a windlass, a smaller rope or chain is used, termed a messenger, which, being attached to the cable at different points, and wound round the capstan, serves to bring the cable forward. But since the introduction of chain-cables this contrivance is not so much required.

When the anchor is brought above water, a tackle from the cathead, called the cat, is hooked on to the shackle of the anchor, and hoisted up; the cathead stopper is then passed, viz., one end of it is fastened round the cathead, and the other is brought through the shackle of the anchor, then over the stopper-cleat, and is belayed round a timber head; the cat is then unhooked, and another tackle called the fish is hooked on just within the flukes, and the arms are hove up so as to lie upon the gunnel, or bill-board; the stock is then made vertical by hauling upon another tackle, called the stock-tackle, in which position the anchor is secured by the stock-lashing for sea. In the event of bad weather, and before commencing a long voyage, the cathead stopper and shank painter is doubled.

The following table contains the dimensions of the parts of anchors of different weights. The letters G. L. denote the greatest and least diameters or breadths.

Weight.	SHANK.							SQUARE.						ARMS.					PALMS.

Besides anchors of the common construction, there are various others of different forms occasionally in use. Small vessels often employ what are termed *grapnels*, which are merely common anchors with four or more arms instead of two, as shown in fig. 6. Following out the same principle, we have the *mushroom* anchor, fig. 7, much employed in the East Indies, to secure the vessels which they term grabs. In this the arms are continued in one segment of a sphere all round; it hence requires no stock, as it takes the ground in any direction. Attempts have frequently been made to introduce anchors with only one arm, but hitherto without any decisive result. A patent for an anchor of this kind, as represented at Plate XXXIX. fig. 8, was taken out by Mr Stuard, which has attracted some notice. "In order," says he, in the specification of his patent, "that this anchor may be sure to fall the right way with the fluke downwards, I would have the shank very short, whereby, when suspended by the cable, it will cant the most, and when it has hold in the ground, the ship will ride safer; as a long shank has more power to loosen and break the ground, and is more likely to be bent or broken from its hold. Let the form of the shank and arm of the anchor be as AA, fig. 8; and, that the parts may be stronger than if made separately and shut together, I would have the bars which compose them in one length, so that there be no weld or joining in the whole length of the shank and arm. The hole B is to receive the ring for the cable, and the hole C is for the stock, which is composed of a wrought-iron bolt, as A, fig. 8, covered with cast-iron at its ends, BB. The palm to be in shape as D, fig. 8, made either entirely of cast-iron, or cast-iron shell filled with lead, which is of much more specific gravity than iron. The back of the palm to be formed either with concave surfaces or flat surfaces, making angles at the centre. The anchor is also to have a small shackle, fixed on the bend of the shank and arm, as at E, fig. 8, for the buoy-rope to be made fast to. The shank may be made without the hole C, and the hole B made octagonal; or if round, it should have a small fillet projecting from the stock, and a small cavity on one side of the hole B to receive it, thus to prevent the stock from turning round; and instead of a ring for the cable, to have a shackle fitted on the stock, on each side of the shank; and, that the shackle may not turn on the stock and fall too low, a stop is to be fixed on each side at the upper end of the shank."—See *Repertory of Arts*, &c., vol. v.

New mooring anchor.

Mooring Anchors are those which are fixed in certain situations in harbours or roadsteads, and to which any of the vessels frequenting the place may be secured. As these are no way limited as to weight like portable anchors, they often consist merely of a large block of stone, such as at fig. 9, with an inner ring fixed in the middle of the upper side; or several such stones may be fastened together so as to act as one mass. Mooring anchors are also often made by choosing one of the largest anchors used for first-rate ships, weighing 80 cwt., and by bending one of the arms close down upon the shank, to prevent it catching hawsers when transporting ships, nets of fishermen, fouling, &c. These anchors are lowered down into the water with a very strong iron mooring chain fastened to the ring, to which the ships are fastened: they are usually made from such as are damaged in one of the flukes or arms. A new kind of mooring anchor of cast-iron was described by Mr Hemman of Chatham, to the *Society for the Encouragement of Arts, &c.*, in 1809, for which he obtained a silver medal from the society. Fig. 5, Plate XXXIX., represents the palm or heavy part of the anchor, made very massive of cast-iron, and of considerable breadth, so that the edge B, or part which enters the ground, may have a great hold; the shank C is made also of cast-iron, and fixed firmly to the head by passing through it, and has a small ring at *a*, where the buoy-rope is fixed; the other end of the shank goes through the stock *dd*, which is formed of two large wooden beams hooped together in the same manner as the stocks for common anchors; the end of the shank projects through the stock, and has a strong wrought-iron shackle E fixed to it by a bolt passing through both, and with this the mooring chain is connected. The great advantage of this over the common mooring anchors arises from its great weight and breadth of edge to act against the ground, and being made of cast-iron. A pair of these anchors, weighing 150 cwt. each, will, with the mooring chains, cost about L.874 less than a pair of the common anchors, which, with their chains, cost L.2472.—See *Transactions of the Society for the Encouragement of Arts, &c.*, vol. xxviii.

Floating-anchor.

This is the name given to a sort of anchor which has often been proposed, but never reduced to practice, for preventing a vessel from drifting, in cases where the great depth of the sea precludes the use of the cable and ordinary anchor. The plan suggested by Dr Franklin seems the most rational. This anchor consisted of two cross bars, secured together in the middle, and having sailcloth fastened to them in the shape of a parallelogram. To the centre of these bars the cable was attached, and being thrown overboard, it was thought the resistance of so large a surface would at least check the rapidity of the ship's motion.

The following is Mr Aylen's plan for anchoring in deep water out of soundings, to prevent vessels from drifting in a calm when in a tide-way, or if disabled:—Hoist out immediately one of the boom-boats, let go the kedge anchor, and veer out 40 or 50 fms. over the bow, and stop it to the ring in the bow and stern of the boat, then veer out from the ship from 70 to 80 fms.

Much attention has been paid of late to the improvement of the manufacture of anchors, and several specimens were sent by the makers to the Royal Exhibition in 1851.

A committee, consisting of five shipowners of London, Liverpool, and Glasgow, with five nominated by the Lords of the Admiralty, was appointed to test the relative merits of these. After trying, on the parade ground of Sheerness dockyard, on the beach at Garrison point, at Blackstakes in the River Medway, and at the Nore, those that were submitted for competition, viz., Admiralty, Aylen's (a modified Admiralty), Honiball (or Porter's), Isaacs' (United States), Lenox's, Mitcheson's, Rodgers', and Trotman's (an improved Porter's), they reported in 1853 that, taking into consideration the results of all the trials to which the anchors had been subjected, they thought it best to record their opinions in the following tabulated forms:—

TABLE showing the relative order in which the several anchors stand with regard to each of the properties essential to a good anchor: the names arranged alphabetically. (Plate XL.)

ANCHORS.	Strength computed from first crack.	Holding long and short scope.	Facility of stowing.	Quick holding.	Quick tripping.	Exemption from fouling.	Facility of sweeping.	Facility of transport in boats.	Fishing in a heavy seaway.	Canting.
Admiralty	4	5	1	2	1	4	1	2	2	2
Aylen	7	4	1	2	3	4	1	2	2	5
Honiball (or Porter's)	2	2	3	4	2	1	4	3	5	3
Isaacs	1	6	4	5	1	1	4	4	5	1
Lenox	6	3	2	1	2	3	2	1	3	2
Mitcheson	Refused this trial.	1	3	1	3	2	3	2	4	4
Rodgers	5	2	1	1	2	4	2	1	1	2
Trotman	3	1	3	3	4	1	4	3	5	5

TABLE shewing the estimated numerical values of the several Anchors in regard to the properties considered essential to a good Anchor.

Note.—This Table only professes to show approximate values, and has no pretensions to mathematical accuracy or precision.

The following is a recapitulation of the order in which the anchors were ranked by the committee, together with their relative per-centage of inferiority or superiority to the Admiralty anchor, the value of which, as given in the foregoing table (18·17), was taken as the standard or unit.

Trotman......... 1·28 or 28 per cent.		Superior to Admiralty Anchor.
Rodgers......... 1·26 or 26 do.		
Mitcheson....... 1·20 or 20 do.		
Lenox........... 1·13 or 13 do.		
Honiball......... 1·09 or 9 do.		
Aylen............ 1·09 or 9 do.		
Admiralty....... 1· the standard.		
Isaacs............ ·73 or 27 per cent. inferior to Admiralty.		

Mr Jonathan Aylen's temporary anchor, Plate XXXIX., made from a broken bower, a stream, and kedge anchor, was completed in four hours (without removing the broken anchor from the bows), on board H.M.S. Hastings of 74 guns, in the Bay of Beyrout in October 1840. That ship having parted the small bower cable, and broken the shank of the best bower anchor, after having previously supplied a ship with one of her spare anchors, was left with only one bower anchor.

Mr Aylen when in command of H.M.S. Rhadamanthus having lost two bower anchors, in Dingle harbour on the west coast of Ireland, rode out a heavy gale in 1847, with his temporary bower anchor.

Supposing both the flukes, and about two feet of the shank and crown of the anchor is gone (invariably the place where all anchors break), the weight of the broken part would be about half the weight of the original, say

In making anchors in the Royal dockyards, the different parts are forged by the steam hammers. In the first place, large slabs or pieces are made about five feet long, and three of them put together, soundly welded, and drawn out of sufficient length for the shank; the arms and palms are forged nearly in the same way; the palms are welded on to the arms, and then the arms welded on to the shank, and the shackle is rivetted on to the shank, the anchor then being complete.

The following is a more particular account of the operations of the anchor-smith on a large scale. The hearth AA of the anchor-smith's forge, see fig. 6, Plate XXXVIII., is built of brick-work raised about 6 or 9 inches above the ground, and 6 or 7 feet square; in the centre is a large cavity to contain the fire; at the back of the hearth a vertical brick wall B is erected, supporting and forming one side of the chimney, which is little more than a dome placed over the hearth, and opening at the top with a low chimney to carry off the smoke. Behind the wall the bellows CD are placed; the noses of the pipes being about the level of the hearth, and coming through the wall, which at that part is defended from the action of the fire by a facing of fire-stone. In this fire-stone the tue-iron is fixed; it is a tube made of wrought iron, and very thick in the substance, that it may not burn away in the fire: the pipes of the bellows are inserted in the tue-iron, and thus convey the stream of air into the centre of the fire.

The bellows are not like those which ordinary smiths make use of; but two large pairs of single bellows CD are placed horizontally by the side of each other, the pipes of both being inserted into the same tue-iron, and directed to blow to the same focus in the centre of the fire: these bellows are exactly like those in use for domestic purposes, which only throw out air when the upper board is pressed down. The two are worked alternately by means of chains *c d* attached to the ends of the upper boards, and united to the end of the working levers HI, placed over each pair of bellows. From the opposite extremities of these levers other chains *e f* are extended to the opposite side of a long lever GG, which moves upon the pivots of a vertical axis E, and is loaded at the ends by heavy weights, to give it *momentum*. Now, two or more men pushing in opposite directions can give it a motion backwards and forwards, and by the communication of the chains and upper levers HI, they will alternately lift up the upper boards CD of the bellows, which being sufficiently loaded, will subside themselves, and force their con-

tents of air into the fire. The men who work the lever G are aided by six or eight more, who place themselves upon the board of one pair of bellows, and as soon as it subsides, they step upon the other pair, which also sinks, and then they return: they have ropes suspended from the roof to enable them to lift themselves, and mount from one bellows upon the other with more ease. The common tue-iron, which is simply a cone of wrought-iron, set with clay into fire-stone, composing the back of the hearth, is very soon burnt by the great heat. The most improved forges, therefore, are now furnished with what is called the water tue-iron, which is made hollow, and water introduced into it to keep it cool. For this purpose two cones are formed of thick iron plate, each with a small aperture at the vertex; these, when put one into the other, are welded together at their bases and their points, so as to form one cone, which is hollow, with a small space all round; two pipes communicate with the hollow, one bringing a continual supply of cold water, and the other conveying away that which is heated by the fire. By this means the tue-iron is kept cool, and can never acquire such a degree of heat as to be burned away: this tue-iron is set with fire-clay into a frame of cast-iron, built up in the brick-work of the wall B.

The anvil K is only a cubic block of cast-iron, placed on the ground much lower than the ordinary smith's anvil; because, as the anchor-smiths always strike by swinging their hammers over their heads, at arms' length, they have more force when the work lies low on the ground than if raised up. At a distance of eight or nine feet from the hearth AA a strong crane-gib LM is erected, so as to turn freely upon the vertical post M. It has no tackle, but the upper beam L, which must be horizontal, has a large iron loop *n* hung upon it, with a roller *o*, which admits it to run freely backwards and forwards upon the beam: the lower end of the loop suspends the anchor; therefore, by moving the rollers along the beam of the gib, and by turning the gib round on its pivots, the anchor can be placed in any position in the fire or upon the anvil. To give motion to the roller *o*, a rack *p* is connected with it; and this is moved by a pinion upon the axis of the wheel *t*, which has an endless rope hanging down, so that a labourer can reach it, and thus remove the anchor nearer or farther from the centre, however great its weight may be. The workmen employ scarcely any other tools than their sledge-hammers, and a few large punches, cutting chisels, and sets or prints, which, when urged by the hammers, will give any particular figure to the work: the hammers are of the largest kind, and weigh from 14 to 18 pounds, according to the strength of the workmen. In the Royal dockyard great use is made of a stamping machine, which the workmen call *Hercules*, and which is very similar to the machine for driving piles. A heavy iron weight N, guided like the ram of the pile engine, is drawn up by the strength of several men, and let fall upon the anchor, to weld the bars, in the same manner as by a forge-hammer. The machine is erected on a large block of stone, which supports the anvil O: two square iron bars PP are fixed on each side of the anvil, in a vertical position, the angles of the bars being placed towards each other. These vertical bars are eight or nine feet high, and are fixed at the top to a beam in the roof of the building in which the machine is placed. The ram N, which weighs $4\frac{1}{2}$ cwt., is fitted to slide up and down between the bars P, having notches in its sides, which receive the angles of the bars: it is drawn up by a rope passing over an iron pulley Q, mounted upon pivots above the top of the vertical bars; and the rope has eight or ten small ones R spliced into it, for as many men to act together (which they do by a motion similar to that of ringing), to elevate the ram, and let it fall upon the iron placed upon the anvil O. The Hercules is placed in the same sweep of the crane as the anvil K, so that the iron can be conveyed to either with equal ease.

The first step in making the different parts of the anchor is to assemble or faggot the bars. For the centre of the mass which is to make the shank, four large bars are first laid together; then upon the flat sides of the square so formed smaller bars are arranged, to make it up to a circle. The number is various, but in large anchors six or eight bars are laid on every side. This circle is surrounded by a number of bars arranged like the staves of a cask; as many as 36 are often used, and they form a complete case for the others. The ends are made up by short bars to a square figure. The faggot is finished by driving iron hoops upon it at sufficient distances; see W in the figure; and it is suspended from the crane in such a manner that it can be moved and turned in any direction, by only one or two men, even when it weighs three tons. For this purpose an iron pulley *k* is hooked to the iron loop *n* of the crane; and a short endless chain *l* passed over the pulley suspends the faggot in its loop. In this manner the weight of the iron is in reality borne by the pivot of the pulley *k*, and the mass can be easily turned round upon its centre to bring any side upwards. To give a power to the man who guides it, one of the four central bars is double the length of the faggot, and projects, see *g*, to form a long lever, by which it is steered; and two holes are made through the end of this bar to insert a cross lever *h*, by which the faggot is turned or rolled round upon its centre. As the faggot hangs very nearly on a balance in the loop of the chain *l*, the man, by weighing on the end of the long bar *g*, can easily raise up its end from the anvil K, and, swinging the crane on its pivots, move it into the fire, which is made up hollow like an oven. To effect this form, the fireman first spreads the coals evenly upon the hearth, and with his shovel or slice makes a flat surface about the level of the tue-hole: he then arranges some large cinders or cakes round in a circle upon this surface, and by other cinders builds it up like an oven or dome, leaving a mouth to introduce the iron. The oven is adapted in size to the magnitude of the mass of iron, and must be brought forwards upon the hearth, to leave a space between its interior cavity and the orifice of the tue-iron; in which space a passage is made from the tue-hole to the fire, and filled up with large lighted coals, and then covered up by small coals. The blast from the bellows passes through these hot coals, in order that the cold air may not enter the fire at once and blow on the iron, but be first converted into flame, which is urged forcibly into the oven, and reverberated from the roof and sides upon the iron placed in the centre. As the floor of the oven is nearly upon a level with the tue-hole, the flame from the coals between it and the fire also plays upon the bottom, and thus heats the iron on all sides. The outside of the dome is covered over with a considerable thickness of small coals, which cake together, and, as the inside of the oven consumes, settle down into a dome again, which the smith aids by striking the outside with the flat of his slice. If the fire breaks out at any place in the roof, the smith immediately repairs the breach with fresh coals, and damps them with water, that they may not burn too fast; for if the inside of the oven burns very fiercely, the flames will not be reverberated so forcibly as when it is in the state of burning cake. Care must likewise be taken to prevent the fire from burning back to the tue-iron. The mouth of the oven should be made no larger than to admit the work; and, that as little heat as possible may escape by the iron, the mouth is filled round it with coals. F is an iron screen hung on hinges, to swing before the mouth of the fire when the iron is withdrawn, that the workmen may not be scorched by the heat.

Anchor.

All the men unite to assist in blowing the bellows, which they work in the manner already described, from half an hour to an hour, according to the size of the anchor, until they have raised the iron to a good welding heat. The mouth of the fire is opened occasionally to inspect the process, and the faggot is turned in the fire if it is not found to be heating equally in every part. Eight men, and sometimes more, are employed to forge an anchor: six of them strike with the hammers, one is stationed at the guide-bar, and the eighth, who is master or foreman, directs the others, and occasionally assists to guide the anchor. When the whole of that part which is in the fire comes to a good welding heat, the workmen leave the bellows and take up their hammers; the coals are removed from the iron, which is swung out of the fire by the man who guides it, assisted by others, and the hot end placed on the anvil; during which time one or two labourers with birch brooms sweep off the coals which adhere to it.

The smiths now begin hammering, one half the number standing on one side, and the other half on the other: they use large sledges weighing from sixteen to eighteen pounds, and faced with steel, striking in regular order, one after the other, swinging the hammers at arms' length, and all striking nearly at the same place. The foreman places himself near the man who guides, and with a long wand points out the part he wishes them to strike, and at the same time directs and sometimes assists the guide to turn the faggot round, so as to bring that side uppermost which requires to be hammered. This is continued as long as the metal retains sufficient heat for welding. This process is exceedingly laborious for the workmen, and is much more effectually performed by means of the Hercules, which strikes such powerful blows upon the iron as to consolidate the bars much more than the strokes of small hammers can do, however long they may be continued. The iron is now returned to the fire, another mouth being opened on the opposite side of the oven, to admit the end or part which has been welded to come through, that a part farther up the faggot may be heated; and when this is done the welding is performed in the same manner as before. Thus, by repeated heatings, the faggot is made into one solid bar of the size and length intended. It is then hammered over again at welding heats to finish it, and make an even surface; and in this second operation the workmen do not leave off hammering as soon as the iron loses its full welding heat, but continue till it turns almost black. This renders the surface solid and hard, and closes all small pores at which the sea-water might enter, and by corroding the bars, expand them, and in time split open the mass of iron.

The shank for an anchor is made larger at the lower end, where the arms are to be welded to it, and is of a square figure. A sort of rebate or scarf, *s*, is here formed on each side of the square, in order that the arms may apply more properly for welding. This scarf is made in the original shape of the faggot, and finished by cutting away some of the metal with chisels whilst it is hot, and using sets or punches, properly formed, to make a square angle to the shoulder of the scarf. The upper end of the shank is likewise square; and the length between these square parts is worked either to an octagon or round, tapering regularly from the lower to the upper end. The hole to receive the ring of the anchor is pierced through the square part at the upper end, first by a small punch, and then larger ones are used till it is sufficiently enlarged. The punch is made of steel; and when it is observed to change colour by the heat, it is struck on the opposite end to drive it out, and is instantly dipped in water to cool it, and another driven in. The projecting pieces or nuts, which are to keep the stock or wooden beam of the anchor, and its place on the shank, are next welded on. To do this the shank is heated, and at the same time a thick bar is heated in another forge: the end of this is laid across the shank, and the men hammer it down to weld it to the shank; then the piece is cut off by the chisel, and another piece welded on the opposite side.

Whilst this process of forging the shank is going on, the smiths of another forge, placed as near as convenient to the former, are employed in making the arms, which are made from faggots in the same manner as the shank, but of less size and shorter, they are made taper (see X), one end of each being smaller than the other: the larger ends are made square, and cut down with scarfs, *r*, to correspond with those, *s*, at the lower end of the shank. The middle parts of the arms are rounded, and the outer extremities are cut away as much as the thickness of the flukes or palms *m*, that the palms may be flush with the upper sides when they are welded on. The flukes are generally made at the iron-forges in the country, by the forge-hammer; but in some yards they are made by faggoting small bars, leaving a long one for a handle. When finished, they are welded to the arms, which have then the appearance of X. The next business is to unite the arms to the end of the shank; and in doing this particular care is necessary, as the goodness of the anchor is entirely dependent upon its being effectually performed. In so large a weld, the outside is very liable to be welded, and make a good appearance, while the middle part is not united. To guard against this, both surfaces of the scarfs should be rather convex, that they may be certain to touch in the middle first. When the other arm is welded, the anchor is complete, except the ring, which is made from several small bars welded together and drawn out into a round rod, then bent to a circle, put through the hole in the shank, and its ends welded together. If the shank or other part is crooked, it is set right by heating it in the crooked part, and striking it over the anvil, or by the Hercules. After all this the whole is heated, but not to a white heat, and the anchor hammered in every part, to finish and make its surface even. This is done by lighter hammers, worked by both hands, but not swung over the head. This operation renders the surface of the metal hard and smooth; and if very effectually performed, the anchor will not rust materially by the action of the sea-water.

The iron from which anchors are made ought to be of the best quality: that kind of it which is called red short will not bear sufficient hammering to weld the bars; and cold short, from its brittleness, is not to be depended upon when the anchor is in use. A good anchor should be formed of the toughest iron that can be procured.

The most extensive establishment for fabricating anchors, &c., is that at Woolwich dockyard, where the Admiralty anchors are made. There the blowing apparatus, the working of the lift and tilt hammers, &c., is all done by a steam-engine of from 14 to 16 horse power. (J. A.)

To steer the ship to her Anchor, is to steer the ship's head towards the place where the anchor lies when they are heaving in the cable, or laying in a strong tideway, that the cable may thereby enter the hause with less resistance, and the ship advance towards the anchor with greater facility. Ships often prevent collision by attention to the helm.

Anchor Ground is a bottom which is neither too deep, too shallow, nor rocky; as in the first the cable bears too nearly perpendicular, and is thereby apt to jerk the anchor out of the ground; in the second, the ship's bottom is apt to strike at low water, or when the sea runs high, by which she is exposed to the danger of sinking; and in the third, the anchor is liable to hood the broken and pointed ends of rocks, and tear away its flukes, whilst the cable, from the

same cause, is constantly in danger of being cut through as it rubs on their edges.

Anchor, in *Architecture*, is a sort of carving somewhat resembling an anchor. It is commonly placed as part of the enrichment of the boultins of capitals of the Tuscan, Doric, and Ionic orders, and also of the boultins of bed mouldings of the Doric, Ionic, and Corinthian cornices, anchors and eggs being carved alternately through the whole buildings.

ANCHUSA, a genus of plants of the natural order of *Boragineæ*. The most noted are *A. officinalis*, once used in medicine as a demulcent, and *A. tinctoria*, or *alkanet*, indigenous in the south of Europe, with a root that yields a fine red to alcohol, wax, and all sorts of oils.

ANCHYLOSIS or Ancylosis (ἀγκύλος), a term in surgery, implying an immovable state of a joint arising from disease.

ANCIENT Demesne, in *English Law*, is a tenure whereby all manors belonging to the crown in the times of William the Conqueror and St Edward were held. The numbers, names, &c., were entered by the Conqueror in the record called *Doomsday Book;* so that such lands as by that book appeared to have belonged to the crown at that time are called *ancient demesne*.

ANCIENTY, in some ancient statutes, is used for eldership or seniority. The elder sister can demand no more than her other sisters, beside the chief mesne, by reason of her ancienty. This word is used in the statute of Ireland, 14th Henry III.

ANCILE, in *Antiquity*, a shield believed to have fallen from heaven, in the reign of Numa Pompilius; at which time, likewise, a voice was heard declaring that Rome should be mistress of the world as long as she should preserve this holy buckler. It was kept with great care in the temple of Mars, under the direction of 12 priests; and, lest any should attempt to steal it, 11 others were made so like as not to be distinguished from the sacred one. These ancilia were carried in procession every year round the city of Rome.

ANCILLARIA, or Ancilla, a Lamarckian genus of minute univalve marine shells, allied to *Olivæ*. See Conchology.

ANCILLON, Johann Peter Friederich, a celebrated historian, and one of the most distinguished members of the Royal Academy of Sciences of Prussia, was born at Berlin in 1766, and died in that city, after a short illness, on the 19th April 1837. His theological studies were commenced at Berlin, and completed at Geneva; and soon after he visited Paris, about the commencement of the revolution, when he became acquainted with Mirabeau. On his return to Berlin he was appointed professor of history in the Royal Military Academy, and a minister of the Reformed Church, in which latter capacity he speedily became distinguished for the eloquence of his style. In 1806 was published his *Tableau des Revolutions*, or a sketch of the revolutions of the political system of Europe from the close of the fifteenth century to the eighteenth, which is perhaps the ablest and most philosophical work on that subject that has appeared. The merits of Ancillon were not overlooked. He was appointed tutor to the Prince Royal of Prussia, and received various appointments from the government. In 1814 he attended his royal pupil to Paris, where he became acquainted with MM. Guizot and De Broglie, and other persons of eminence. He was also much employed by his government in diplomatic affairs, and was made a counsellor of state. His other writings are as follows: *Melanges de Littérature et de Philosophie; Essais Philosophique, &c.; Essais de Philosophie, de Politique, et de Littérature; Sermons, &c.* See Preliminary Dissertation, No. I. of this work.

ANCLAM. See Anklam.

ANCONA, a maritime city of Italy, in the States of the Church, and capital of a delegation of the same name. It is pleasantly situated on the shores of the Adriatic, occupying a slope between two hills, on one of which stands a cathedral, and on the other a citadel; but the streets are generally narrow and irregular. It possesses some fine buildings, such as the exchange, town-house, and lazaretto; is the seat of a bishop, has a court of appeal, and a public library of nearly 10,000 volumes. Its port, which is the best on the Adriatic, is defended by several forts, and protected by two moles. A magnificent triumphal arch of white marble adorns the ancient mole. It was erected in honour of the emperor Trajan, who greatly embellished the city, and built this mole. An arch, dedicated to pope Benedict XIV. decorates the new mole, which has at its extremity a lighthouse with a revolving light. The principal manufactures of Ancona are silk, sail-cloth, paper, leather, and wax candles; the exports are corn, wool, wax, bacon, and tallow; and the imports consist of colonial goods, drugs, and metals. Ancona has been a free port since 1732. The number of vessels that entered its port in 1842 was 1522, with an aggregate burthen of 109,813 tons. It has communication by steam with Trieste, Corfu, Patras, Syra, Athens, Smyrna, Constantinople, and Alexandria. Pop. 32,000, including many Greeks, and about 5000 Jews. Long. 13. 30. 35. E. Lat 43. 37. 42. N.

This city was founded about 380 B. C. by Greek colonists, who had fled from Syracuse to escape the tyranny of the elder Dionysius. It rose rapidly into importance, and became celebrated for its purple dye. The exact time of its subjection to the Romans is uncertain; but it was taken possession of by Cæsar immediately after he crossed the Rubicon. Of its celebrated temple of Venus no traces remain, but it is supposed to have occupied the site of the present cathedral. In the middle ages it was an independent republic, and continued such until 1530, when Pope Clement VII. took possession of the town, and built the citadel under the pretext of defending it against the Turks. In 1798 Ancona was taken by the French, and in the following year it surrendered to the combined forces of the Austrians, Russians, and Turks, after a long and gallant resistance, under the direction of General Meunier. The French captured it a second time in 1801; but in the following year restored it to the Pope.

It afterwards formed part of the kingdom of Italy, till 1814, when it was again united to the papal dominions. In 1832 a party of French landed unexpectedly and took possession of the citadel, which they refused to evacuate so long as any Austrian troops remained within the Papal States: and this demand having been complied with, the French troops withdrew in 1838.

ANCOURT, Florent Carton d', an eminent French comic writer and actor, was born at Fontainbleau, on the 1st November 1661. He died on the 6th December 1726, being 65 years of age. The plays which he wrote were all, with one exception, comic. They have been frequently reprinted, and form, in the best edition, namely, that of 1760, a collection of 12 vols. 12mo.

ANCUS Marcius, the fourth king of the Romans, succeeded Tullus Hostilius 640 years before Christ. He defeated the Latins, subdued the Fidenates, conquered the Sabines, Volsci, and Veientines, enlarged Rome by joining to it Mount Janiculum, and made the harbour of Ostia. He died about 617 years before the Christian era. In his reign many of the conquered Latins were incorporated with the Roman state, and not receiving the full franchise, formed the first elements of the Roman plebs.

ANCYLOBLEPHARON (from ἀγκύλος, *bent*, and βλέφαρον, *an eyelid*), a disease of the eye, which closes the eyelid.

ANCYLOGLOSSUM (from ἀγκύλος, *crooked*, and γλῶσσα *the tongue*), a contraction of the ligaments of the tongue. Some have this imperfection from their birth, others from some disease. In the first case, the membrane which supports the tongue is too short or too hard; in the latter, an ulcer under the tongue, healing and forming a cicatrix, is sometimes the cause. These speak with some difficulty. Those who have this imperfection by nature are late in acquiring the power of speech; but having acquired it, they soon speak properly. Such persons are commonly called *tongue-tied*.

ANCYRA. See ANGORA.

ANDALUCIA, an extensive region in the south of Spain, on the Mediterranean Sea. It is divided into eight provinces, viz., Almeria, Granada, Jaen, Malaga, Cadiz, Cordova, Huelva, and Sevilla. Though its surface is very unequal, and its soil and climate vary with the elevations of the land, it must be considered the most rich and delightful of all the divisions of the peninsula.

The geographical denomination should strictly be confined to the ancient kingdoms of Sevilla and Cordova, divided into High and Low Andalucia; but the name is now generally extended so as to include also the kingdoms of Jaen and Granada. This will comprehend all the beautiful and picturesque south of Spain, from Lat. 30. 42. to Lat. 36. N., and between Long. 1. 45. and Long. 7. 15. W. It is bounded on the north by the chain of the Sierra Morena; on the east by the Sierras of Segura and Cazorla, and partly by the Mediterranean; on the south by the Mediterranean, the Straits of Gibraltar, and the Atlantic; and on the west by Portugal. Its area is computed at 3283 square leagues. It is divided into numerous valleys of varied extent by mountain arms that traverse it in many directions. Some of these are shaggy with wood, others are denuded of vegetation, while some of the loftier mountains are partially covered with perennial snow, which is a luxury highly prized by the inhabitants during their fervid summers. On many occasions we have found the heat in the shade ranging from 86° to 96° Fahr.; but this temperature is abated by refreshing sea breezes along its extensive coasts. The winter is so mild that the nightingale continues its song in the groves throughout the year, and if ever a flake of snow descends on the plains, it melts almost on touching the ground. Many of the less elevated mountains are clothed with vines, which produce an abundant supply of delicious wines; or they are covered with excellent pasture.

In the bowels of the mountains the Carthaginians and the Romans sought for silver, and found gold in some of the streams. Valuable mines of argentiferous galena, and some copper ores are now wrought; and no country abounds more in beautiful marbles and serpentines. These are much used in the decorations of the churches.

The principal river of Andalucia is the Guadalquiver, with its numerous affluents. It rises in the Mountains of Jaen on the confines of Murcia, and traverses Andalucia in a south-west direction, passing by the cities of Andujar, Cordova, Palma, and Sevilla, and falls into the sea at San Lucar.

Its principal affluents have various names, as the Rio Huelva, Rio Biar, and Rio Guadiato, from the north-west; from the south-east the Darro and the Genil, which water the lovely *Vega* or plain of Granada; while the Rio Gaudix, Rio Guardal, Rio Guadalimar, and Rio Corbones, flow into the Guadalquiver in other directions. Besides these, the noble stream of the Guadiana washes a part of its western frontier.

The minor rivers of this fine province that flow directly into the sea are as follows, commencing on the west side: the Rio Tinto, falling into the sea at Huesca; Rio Guadalete, at Santa Maria; Rio Barbate, into the Bay of Trafalgar; Rio Guadranque, into the Bay of Gibraltar; Rio Verde, near Marbella; Rio Guadaljore, near Malaga; Rio Guadalpo, at Motril; Rio Adra, Rio Almeria, and Rio Almanzora, falling into the Mediterranean.

The mountains in Andalucia are the Sierra Bermeja and its branches, which, with Sierra Blanquilla, constitute part of the larger sierras of Ronda, Filabres, Bujo, Javal, Cohol; the sierras of Leita, Quesada, and Torres in Jaen, which unite with the Sierra Morena and Sierra Segura; the sierras of the Alpujarras, between the Sierra Nevada and the Sierra of Gador, with the sierras of Contraviesa, and Cazorla; Susiana and Constantina.

When the traveller descends from the table-land of New Castile into Andalucia, he suddenly feels that he has entered a very different climate. The temperature of the air, the total change in vegetable forms, almost indicate a tropical region, especially as he approaches the coast. The more common European plants there give place to the wild olive, the caper bush, the aloe (*agave*), the cactus, the evergreen oak, and fragrant groves of orange and lemon trees; while the place of furze and heaths is supplied by the astragalus lignosus, and the prickly palmated leaves of chamærops humilis; and in a few places he may behold the graceful form of the date-palm depicted on a sky of the serenest blue. On the coasts of the Mediterranean, about Marbella and Malaga, the sugar-cane is successfully cultivated; and no inconsiderable quantity of silk is produced in the same regions. The sides of the hills are often covered with extensive vineyards; and the ill-cultivated and generally uninclosed plains wave with luxuriant crops of wheat, or are green with immense fields of melons cultivated with the plough. The horses and bulls of Andalucia are celebrated all over Spain; sheep and swine are extensively bred, and game is abundant.

The general statistics of Andalucia will be best seen by reference to the two adjoined tables, drawn up by Don Pascual Madoz, for his *Diccionario Geografico-Estadistico-Historico de España*, a valuable and laborious work published at Madrid in 1847.

By this table the population of all Andalucia amounts to 2,305,950: the "ratable riches" to about L.3,706,000 sterling, and the contributions levied on it to L.933,000.

The natives of Andalucia are a lively people, given to pleasure, and of a very ardent imagination, superstitious, boastful, and unwarlike, but ready-witted and good-humoured. Their forms are not tall, but they are vigorous and well-made, generally with jet black hair, dark eyes, and a skin less fair than the natives of Aragon and the north of Spain. The women are considered as the handsomest in all the peninsula, with most brilliant eyes, and very graceful figures. The dialect spoken in Andalucia is said by Castilians to retain something of the Arabesque, in the use of certain words that are not reckoned pure *Castilian* or Spanish, and in a greater profusion of gutturals than is used in the central provinces; circumstances not to be wondered at, when we reflect that for seven centuries the Arabians were the dominant race in Andalucia.

The original population of this region is supposed to have been from Mauritania. We know that its advantageous position for commerce, its general products, and its mines, early attracted the adventurous merchants of Tyre and Carthage to its shores; and it became an important possession to the Phœnicians and Carthaginians until it was wrested from the latter by the Romans. Before that period it had many flourishing cities; as Gades, Emerita, Hispalis, Corduba, Malaca, and Carteia. From the Romans it passed successively to the Visigoths, the Arabs, and the present Spanish race.

For the civil history of this province, see SPAIN.

ANDAMAN Islands. These islands, which are situated on the eastern side of the Bay of Bengal, are a continuation of the archipelago which extends from Cape Negrais to Atchein Head, stretching from Lat. 10. 32. to 13. 40. N., and from Long. 90. 6. to 92. 59. E. They are called the Great and the Little Andaman. The Great Andaman, which is the northernmost, is 140 miles in length, and only 20 in breadth. It was formerly supposed to be one island; but two straits have been discovered, which open a clear passage into the Bay of Bengal, and divide the Great Andaman into three islands. The Little Andaman, which lies 30 miles south of the Great Andaman, is 28 miles long and 17 broad. It does not afford any good harbour, though tolerably safe anchorage may be found near its shores. These islands have an extremely moist temperature. They are situated in the direct current of the south-west monsoon; and the central mountains, some of the lofty peaks of which, as Saddle Peak in the Large Andaman, rise to the height of 2400 feet, intercept the clouds, which, for about eight months in the year, pour down incessant torrents of rain on the plains below. According to a meteorological table kept by an officer resident on the island, 98 inches of water appear to have fallen in the course of seven months. On the whole, however, the temperature is milder than in Bengal, and the heat not so intolerable.

The island is totally uncultivated, and the savage inhabitants glean a miserable subsistence from the spontaneous produce of the woods, in which the researches of the Europeans have hitherto found little that is either palatable or nutritious. The principal trees are the banyan-tree, the almond-tree, the oil-tree, which grows to a great height and yields a very useful oil; the poon, the dammer, the red wood, which for furniture is little inferior to fine mahogany; the ebony, the cotton-tree, the soondry, chingry, and beady; the Alexandrian laurel, the poplar, a tree resembling satin-wood, bamboos, cutch, the melon, aloes; the iron-tree of stupendous size, whose timber almost bids defiance to the axe of the wood-cutter. There are many other trees well adapted for the construction of ships; and, as in all the equatorial forests, there are numberless creepers and ratans, which surround the stems of the trees, and are so firmly interlaced together, that the forests are impervious, except a road be previously cut through them.

The only quadrupeds seen on the island are hogs, rats, and the ichneumon; also the iguana of the lizard tribe; all which are very destructive to poultry. There are several species of snakes and scorpions, by which the labourers employed by the British in clearing away the underwood were frequently stung; but in no instance did the sting prove mortal. The patient was frequently affected with violent convulsions, which gradually yielded to the operation of opium and eau-de-luce.

Fish abound on the shores, and are caught in great numbers during the prevalence of the north-east monsoon, when the weather is mild: gray mullet, rock cod, skate, and soles, are among the best. There are, besides, various other species, such as guanas, sardinas, roe-balls, sable, shad, prawns, shrimps, cray-fish, a species of whale, and sharks of an enormous size. Shell-fish are in great plenty, and oysters of an excellent quality. The shores abound in a variety of beautiful

shells, such as gorgonias, madreporas, murex, and cowries, with many other sorts equally beautiful.

Birds are not numerous, and they are extremely shy. Doves, parroquets, and the Indian crow, are the most common. Hawks from the neighbouring continent are sometimes seen hovering over the tops of trees; and a few aquatic birds, such as the king-fisher, a sort of curlew, and the small sea-gull, frequent the shores. Within the caverns and recesses of the rocks are found the edible birds' nests so highly prized among the Chinese, and now occasionally brought into Britain.

The whole population of the islands does not exceed 2000 or 2500, and they are probably the most uncivilised people on the face of the globe. They are far below the ordinary scale of barbarism; and in their modes of subsistence, and in their dwellings, they rise very little above the brute creation. They wear no clothes, and seem insensible to any feeling of shame from the exposure of their persons. The woods supply them with little in the way of food. They are provided with no pot or vessel that can bear the action of fire, and they cannot therefore derive much advantage from such esculent herbs as the forests may contain. The cocoa-nut, which thrives so well in the neighbouring islands, is not found in the Andamans, though the natives are extremely fond of it. The fruit of the mangrove is principally used by them. Their principal food consists of fish, in quest of a precarious meal of which they climb over the rocks, or rove along the margin of the sea, often without success during the tempestuous season; but they eagerly seize on whatever else presents itself, such as lizards, iguanas, rats, and snakes. Their diseased and extenuated figures sufficiently testify that they have no abundant or wholesome nourishment. In stature the inhabitants of the Great Andaman seldom exceed five feet; their limbs are disproportionably slender, their bellies protuberant, their shoulders high, and heads large; and, what is singular and unaccountable, they have all the characteristic marks of a degenerate race of negroes, with woolly hair, flat noses, and thick lips; their eyes are small and red, their skin of a deep sooty black, while their countenances exhibit a mixed expression of famine and ferocity. Lieutenant Alexander describes the inhabitants of Little Andaman as far from being a puny race. When he landed in a boat he counted sixteen strong and able-bodied men, many of them very vigorous. The ingenuity of these savages is principally seen in the fabrication of a few simple weapons on which they depend for their subsistence. These are a bow from four to five feet long, with arrows of reed, headed with fish bone or wood hardened in the fire, a spear of heavy wood sharply pointed, and a shield made of bark. With these implements they shoot and spear the fish, which abound in their bays and creeks, with surprising dexterity. The settlement of these islands, with their negro inhabitants, so widely different in their appearance not only from all those of the Asiatic continent, in which the Andamans are embayed, but also from the natives of the Nicobar islands, presents a curious problem, which has never been satisfactorily explained. It is supposed, however, by Symes, that the original stock must have been settled on the island by the accidental shipwreck of some Arab slave-ship. The English made a settlement on the larger Andaman in the year 1793. Their object was to procure a commodious harbour on the east side of the Bay of Bengal, to receive and shelter ships of war during the continuance of the north-east monsoon; also to provide a place of reception for convicts sentenced to transportation from Bengal. But the settlement, proving unhealthy, was abandoned in 1796. These islands, together with the Nicobar and other smaller islands, were included by Ptolemy in the general appellation of *Insulæ Bonæ Fortunæ*, and were supposed by him to be inhabited by a race of anthropophagi, though there are no proofs of the modern inhabitants being addicted to cannibalism. (Symes' *Embassy to Ava;* Alexander's *Travels from India to England, comprehending a Visit to the Burman Empire, &c.;* Hamilton's *Gazetteer.*) (D.B—N.)

ANDANTE, in *Music*, signifies a movement moderately slow, between *largo* and *allegro.*

ANDEGAVI, a Gallic tribe, whose chief town was Juliomagus, now Angers.

ANDELYS, LES, an arrondissement in the department of the Eure, in France. It extends over 392 square miles, or 250,840 acres, is divided into six cantons, which are subdivided into 134 communes, and in 1851 contained 64,717 inhabitants. The chief town, of the same name, had 5069 inhabitants. It is four miles from the Paris and Rouen Railway. The manufactures are fine cloths, cotton, bonnets, &c.

ANDENA, in *Old Writings*, denotes the swath made in the mowing of hay, or as much ground as a man could stride over at once.

ANDENNE, a town of Belgium, capital of a canton of the same name, arrondissement and province of Namur, on the right bank of the Meuse, ten miles east of Namur. It is famous for its manufactures of porcelain and tobacco-pipes. In the neighbourhood are beds of pipe-clay, quarries of marble, and mines of iron and lead. Pop. in 1850, 5316.

ANDERAVIA. See INDERABIA.

ANDERNACH (the ancient *Antunacum*), a town in the Prussian province of the Lower Rhine and district of Coblenz, ten miles north-west of that town. It is situated on the Rhine, and was once strongly fortified, but its walls are now in ruins. It has tin and leather works; and exports mill-stones and pounded tufa, used as a cement, which hardens under water, and is much used by the Dutch in constructing their dikes. Pop. in 1849, 3785. Long. 7. 4. E. Lat. 50. 57. N.

ANDERSON, ADAM, was born in Scotland in 1692. He was a clerk for forty years in the South Sea House in London, where he published a large work entitled *Historical and Chronological Deduction of the Origin of Commerce, containing a History of the Great Commercial Interests of the British Empire,* &c., which is voluminous and heavy; but he seems to have anticipated in some of his speculations the opinions of later times. It was first published in 1762, in two vols. fol. A third edition appeared in 1797–9, in four vols. 4to, the last volume being an appendix and continuation by the editor, Mr Walton. Anderson died in 1765.

ANDERSON, *Alexander*, a very eminent mathematician, who flourished in the early part of the seventeenth century. He was born at Aberdeen, but passed over to the Continent, and settled as a private teacher or professor of mathematics at Paris, where he published or edited, between the years 1612 and 1619, various geometrical and algebraical tracts, which are conspicuous for their ingenuity and elegance. It is doubtful whether he was ever acquainted with the famous Vieta, master of requests at Paris, who died in 1603; but his pure taste and skill in mathematical investigation had pointed him out to the executors as the person most proper for revising and publishing the valuable manuscripts of that illustrious man, who had found leisure, in the intervals of a laborious profession, to cultivate and extend the ancient geometry, and, by adopting a system of general symbols, to lay the foundation and begin the superstructure of algebraical science. Anderson did not come forward, however, as a mere editor; he enriched the texts with learned comments, and gave neat demonstrations of those propositions which had been left imperfect. He afterwards produced a specimen of the application of geometrical analysis, which is distinguished by its clearness and classic elegance.

Of the time of this able geometer's birth and death we are ignorant. His brother David Anderson, a small proprietor in Aberdeenshire, but engaged in business, had likewise a strong turn for mathematics and mechanics, which, joined to great versatility of talent, made him be regarded by his neighbours at that period as a sort of oracle. The daughter of this clever and active burgess was married to John Gregory, minister of Drumoak, in that county, father to the celebrated James Gregory, inventor of the reflecting telescope; and is supposed to have com-

municated to her children that taste for mathematical learning which afterwards shone forth so remarkably in the family of the Gregorys.

The works of Anderson amount to six thin 4to volumes, which are now very scarce. (J. L.)

ANDERSON, *Sir Edmund*, a younger son of an ancient Scottish family settled in Lincolnshire. He was some time a student of Lincoln College, Oxford, and removed from thence to the Inner Temple, where he applied himself diligently to the study of the law, and became a barrister. In 1582 he was made lord chief-justice of the common pleas, and in the year following was knighted. He held his office to the end of his life in 1605. His works are, 1. Reports of many principal Cases argued and adjudged in the time of Queen Elizabeth in the Common Bench, Lond. 1644, fol.; 2. Resolutions and Judgments on the cases and matter agitated in all courts of Westminster in the latter end of the reign of Queen Elizabeth, Lond. 1655, 4to.

ANDERSON, *James, LL.D.*, was born at the village of Hermiston, in the county of Edinburgh, in the year 1739. His parents were in humble life, and had possessed a farm for some generations, which he was destined to inherit and to cultivate. At an early age he lost his parents: his education, however, was uninterrupted; and conceiving that an acquaintance with chemistry would promote his professional success, he attended a course of lectures on that science, then delivered by Dr Cullen.

Enlarging the sphere of his employments, Anderson forsook his first possession, and rented in Aberdeenshire a farm of 1300 acres, which was then nearly in a state of nature. But previous to this he became known to men of letters, by some essays on planting, which, under the signature "Agricola," he ventured to commit to the world through the medium of the *Edinburgh Weekly Magazine*, in 1771.

After withdrawing from his northern farm, where he resided above 20 years, he settled in the vicinity of Edinburgh. His agricultural speculations were still continued; and when a parliamentary grant was about to be proposed to Mr Elkington for a particular mode of draining land, he reclaimed the discovery as having been made by himself many years anterior. In 1791 Dr Anderson projected a periodical publication called *The Bee*, consisting of miscellaneous original matter, which attained the extent of 18 volumes in octavo. It was published weekly, and a large proportion of it came from his own pen. From this period till 1803 he gave to the world a number of publications chiefly on agricultural subjects, which had no small influence in advancing national improvements. He has the great merit of being the first who satisfactorily unfolded the true theory of rent. He showed by an original and able analysis that rent is not the recompense of the work of nature, nor a consequence of land being made private property, but that it depends on the various degrees of fertility of land, and on the circumstance of its being impossible to apply capital indefinitely to any quality of land, without receiving from it a diminished return.

Dr Anderson remained in his retreat, enjoying the cultivation of his garden; and after a gradual decline, partly occasioned by the over-exertion of the mental energies, he died in the year 1808, aged 69. He was twice married; first, to Miss Seton of Mounie; secondly, to an English lady. By his first marriage he had thirteen children, six of whom survived him. During a period of overstrained political fervour, certain papers formed part of the periodical works already referred to, which were thought to contain a libel on the government. Although Dr Anderson's principles were noted for attachment to the existing administration, he was called upon to give up the author of the obnoxious compositions, which he steadily refused, and, even in the face of the civil magistrates, charged his printers not to violate their fidelity to him and the author in betraying his name. The business terminated here, until a factious individual insinuated to the same magistrates that the compositions had proceeded from one of the supreme judges, whose party politics were avowedly hostile to those of government. Dr Anderson having learned the reproach, hastened to relieve the object of it by divulging the name of the real author, who, to the universal surprise of the public, proved to be none other than the traducer himself.

ANDERSON, *James, W.S.* This learned and indefatigable antiquary was the son of the Rev. Patrick Anderson, one of the many victims whom the tyranny of the government of his country condemned in 1678 to imprisonment on the Bass Rock, for attending a conventicle. This son was born at Edinburgh in August 5. 1662, and was educated to the legal profession, in which he became *Writer to the Royal Signet*, a station in Scotland which may be considered as equivalent to an *Attorney* and *Notary Public*.

His character and acquirements stood so high, that just before the Union the Scottish parliament entrusted him with preparing for publication what remained of the public muniments of the kingdom; and in their last session supplied him with L.1940 sterling for defraying the expenses of that great undertaking. At this work he laboured for many years with great judgment and perseverance; but it was not completed at his death in 1728. The work was published under the care of the celebrated Ruddiman; who in an excellent preface laments the death of his learned countryman, and adds, "tantumque non ad umbilicum produxerat ὁ πάνυ Jacobus Anderson." This work is the great "DIPLOMATA ET NUMISMATA SCOTIÆ," "a publication," says the sagacious but often too caustic Pinkerton, in his *Enquiry*, "never to be excelled in elegance, and scarcely in exactness." The labour of preparing this great national work had impaired his health and his fortune, notwithstanding the parliamentary aid; and soon after his death, the numerous plates, engraved by Sturt, were sold for L.530; but these plates are now lost, and the book has become exceedingly scarce. After the union of the crowns, Anderson was appointed in 1715 Postmaster-General for Scotland, as some compensation for his valuable labours; but in the political struggles of 1717 he was ungraciously deprived of this office; and never again obtained any reward for his important services to his country. (T. S. T.)

ANDERSON, *John*, professor of natural philosophy in the University of Glasgow, was born in the parish of Roseneath in Dumbartonshire in 1728. He finished his education in that University, where he first became professor of oriental languages in 1756, but in 1760 was appointed to the chair of natural philosophy, a subject more suited to his tastes and acquirements. In this department he laboured assiduously to apply scientific knowledge to the improvement of the mechanical arts. For this purpose he studied their processes in the various workshops of the city, and thus acquired an intimate acquaintance with those operations, which fitted him in an eminent degreee for the great object which seems to have been his chief aim, the scientific instruction of the operative mechanic. He is, in fact, to be considered the father of those Mechanics' Institutions which have since been so widely disseminated in this and other countries. He soon began to open classes for their instruction in the principles of their arts, in which his familiar extempore discourses were illustrated by appropriate experiments. The working mechanic received every encouragement from this eminent man to attend his courses, at which they were received in their working dresses.

His anxiety for the improvement of the humble mechanic was not confined to his personal exertions. Shortly before

 his death in 1796, he bequeathed the whole of his property to 81 trustees, for the purpose of founding an institution for educational purposes in Glasgow. He had seemingly intended it as a sort of rival to the university in which he was himself a professor; for his will mentions the founding of four halls or colleges with nine professors in each, for the faculties of arts, medicine, law, and theology! But the trustees found the funds entrusted to them utterly inadequate to so gigantic a scheme; and they contented themselves with founding what is now called the *Andersonian Institution*, or sometimes less correctly *University*.

It was opened in 1797, by the appointment of Dr Thomas Garnett as professor of natural philosophy, who commenced with a popular course of lectures, which was attended by a considerable audience of both sexes. In 1798 a professor of mathematics and geography was appointed; and the institution has since had the aid of several able teachers. In 1799 Dr Garnett was succeeded by Dr Birkbeck, who had the merit of introducing in the institution a system of scientific instruction annually to 500 operative mechanics, free of all expense to the pupils. On the removal of this excellent man to the London Royal Institution, he was succeeded by Dr Andrew Ure in 1804; and Dr Ure by Dr William Gregory. This institution still flourishes; and has been of vast benefit to the humbler classes of the citizens of Glasgow. (T. S. T.)

ANDERSON, *Robert*, the fourth son of William Anderson, and of Margaret Melrose his wife, was born at Carnwath, in Lanarkshire, on the 7th of January 1750. His father was a *feuar*, that is, a person who possessed some small parcels of real property by the tenure of a perpetual lease. His first destination was for the church: in the year 1767 he was sent to the university of Edinburgh, and in due time was enrolled among the students of divinity. His schoolfellow, James Græme, who had entered the university at the same time, and with the same views, died of consumption in 1772, in the 23d year of his age; and, after a short interval, his faithful friend published a collection of *Poems on several occasions, by James Græme*. Edinb. 1773, 12mo. About this period he relinquished the study of divinity, and betook himself to the study of medicine. He was for a short time employed as surgeon to the dispensary at Bamborough Castle in Northumberland; and in a neighbouring town he then formed connections which had no small influence on his future destiny. On the 25th of September 1777, he married Anne, the daughter of John Gray, Esq. of Alnwick, who was related to the noble family of that name. Returning to Scotland he took the degree of M.D. at St Andrews on the 20th of May 1778, after having been duly examined by the professor of physic. He now began to practise as a physician at Alnwick; but his general habits were rather those of speculation than exertion, and a moderate provision, acquired by his marriage, had emancipated him from the necessity of professional labour. In 1784 he finally returned to Edinburgh, where he continued to reside for the period of 46 years, in a condition of life removed from affluence, but perfectly compatible with genuine independence and comfort. His amiable and affectionate wife died of consumption on the 25th of December 1785, in the 39th year of her age. In 1793, after having remained a widower for eight years, he married Margaret, the daughter of Mr David Dall, master of Yester school in the county of Haddington.

For several years his attention was occupied with his edition of *The Works of the British Poets, with Prefaces Biographical and Critical*, which was published at Edinburgh, and extends to 14 large octavo volumes. The earliest volume, which is now the second in the series, was printed in 1792-3; the 13th was printed in 1795, and another volume was added in 1807. He was frequently solicited to revise his Lives of the Poets, and publish them in a separate form, but after having collected some materials for such a work, he finally abandoned the design. In the mean time he had published *The Miscellaneous Works of Tobias Smollett, M.D., with Memoirs of his Life and Writings*. Edinb. 1796, 6 vols. 8vo. But the most able and elaborate of his productions is the third edition of his *Life of Samuel Johnson, LL.D., with Critical Observations on his Works*. Edinb. 1815, 8vo. The same service which he rendered to Dr Smollett he afterwards extended to Dr Moore, having published *The Works of John Moore, M.D., with Memoirs of his Life and Writings*. Edinb. 1820, 7 vols. 8vo. At an earlier period he had published *The Poetical Works of Robert Blair; containing the Grave, and a Poem to the Memory of Mr Law: to which is prefixed the Life of the Author*. London, 1794, 8vo. And his latest publication was *The Grave and other Poems, by Robert Blair; to which are prefixed some Account of his Life, and Observations on his Writings*. Edinb. 1826, 12mo.

Dr Anderson contributed his ready aid to many different publications, and was always influenced, not by the love of money but by the love of literature. With many eminent men in England, Ireland, and America, he maintained a literary correspondence; and having survived most of his lettered contemporaries, he enjoyed the esteem and consideration of a second and even of a third generation. No part of his character was more conspicuous than his uniform and unabating zeal to promote the success of young men who discovered any promise, however moderate, of literary talent; and some of the more distinguished writers of our own age and nation were not without their obligations to his disinterested friendship. Mr Campbell dedicated to him his earliest and most popular publication, *The Pleasures of Hope*. Thomas Brown, John Leyden, and Alexander Murray, who all died at too early an age, were among the most eminent of his young friends. For Dr Brown, who became professor of moral philosophy in the university of Edinburgh, he entertained a very cordial esteem, which suffered no abatement or interruption. Another prominent feature of his mind was his ardent regard for the civil and religious liberties of mankind. This characteristic he displayed from the first years of manhood till the last day of his earthly existence.

His bodily frame had never been robust; but the uniform temperance and regularity of his habits contributed to prolong a life which was marked by cheerfulness and benevolence. His faculties, mental and corporeal, betrayed few or no symptoms of old age. During the greater part of his last winter he was confined to his own house by what was considered as a common cold, and was attended by his friend and contemporary Dr Hamilton. Of the immediate prospect of death, he spoke, not merely with resignation, but even with cheerfulness; with the subdued but confident hope of one who had long and habitually reposed on the assurances of the Christian faith. He died on Saturday, the 20th of February 1830, after having completed the 80th year of his age; and, according to his own directions, his remains were interred in Carnwath churchyard. His eldest daughter, Anne Margaret, was married in 1810 to David Irving, LL.D., and died in 1812, leaving an only son. His second daughter, Margaret Susannah, lived to deplore the loss of a parent whose declining years she had soothed by the most exemplary attention to all his wants and wishes. (D. I.)

ANDES. The Andes form a mighty mountain chain running nearly parallel to the western coast of South America. The central ridge extends in an undivided chain from the Rio Atrato, at the Isthmus of Darien, in Lat. 8. N., to the Cordilleras of Vilcanoto and Cuzco, in Lat. 15. 50. S., where it separates into western and eastern ridges, that in-

close the extensive and elevated valley of Desaguedero, and exhibit some stupendous peaks that almost rival the altitude of the Himalayas of the East. After running parallel to each other to Lat. 19. 30. S., they again coalesce, and constitute one central chain to the Straits of Magellan, in Lat. 53. The Andes of South America then have a range of about 4200 miles. The most western of the two longitudinal ridges runs parallel to the Pacific, and is called the *Cordillera* of the Coast; the eastern chain is generally termed the *Cordillera* of the Interior, and its northern prolongation *Cordillera Real.* The valley of Desaguedero extends from Lat. 15. 5. to Lat. 19. 30. S., with a varying breadth from 35 to 60 miles, presenting an area of 16,000 square geographical miles. It contains the celebrated Lake of Titicaca, the cradle of Peruvian civilisation. It was on the shores of this lake that Manco Capac, the first Inca, was miraculously discovered by the Quichu, the ancestors of the Peruvians.

The Andes send out, nearly at right angles from their colossal ridge, between the latitudes of 14° and 20° south, three dependent branches, called by the Spaniards also *Cordilleras.* Of these secondary chains, the *first* and most northern is that of the coast of Venezuela, which is likewise the highest and narrowest. With an irregular altitude, it bends eastwards from the Atrato, forming the Sierra of Abibé, the mountains of Cauca, and the high savannahs of Folu, till it reaches the stream of Magdalena, in the province of St Martha. It contracts as it approaches the Caribbean Sea, at Cape Vela; and thence extends to the mountain of Paria, or rather the Galley Point, in the island of Trinidad, where it terminates. This secondary chain attains its greatest known elevation where it rears the snowy summit, or Sierra Nevada, of St Martha and of Merida, the former being nearly 14,000 and the latter above 15,000 feet in altitude. These insulated mountains, covered so near the equator with eternal snow, yet discharging boiling sulphurous water from their sides, are higher than the Peak of Teneriffe, and can be compared only with Mont Blanc. In their descent they leave the Paramo or lofty desert of Rosa and of Mucachi; and on the west side of the Lake Maracaibo they form long and very narrow vales, running from south to north, and covered with forests. At Cape Vela the mountain chain divides into two parallel ridges, which form three confined valleys ranging from east to west, and having all the appearance of being the beds of ancient lakes. These ridges, of which the northern is the continuation of the Sierra Nevada of St Martha, and the southern the extension of the snowy summits of Merida, are united again by two arms which seem to have been placed by the hand of nature as dikes to confine the primeval collections of water. The three valleys thus inclosed are remarkable for their elevation above the sea, rising like steps one above another, the eastmost, or that of the Caraccas, being the highest. This plain was found by Humboldt to be elevated 2660 feet, while the basin of Aragua was only 1350 feet in height, and the Llanos, or reedy plains of Monai, spread within 500 or 600 feet above the level of the shore. The lake of the Caraccas appears to have forced a passage for itself through the *quebrada* or cleft of Tipé, while that of Aragua has been gradually dissipated by a slow process of evaporation, leaving some vestiges of its former existence in pools charged with muriate of lime, and in the low islets called *Aparecidas.* The medium height of the Cordillera of the coast is about 4000 or 5000 feet; but its loftiest summit, next to the Sierra Nevada of Merida, is the *Silla* (or saddle) of the Caraccas, which was visited by Humboldt, and ascertained from barometrical measurement to have an elevation of 8420 feet. Farther to the eastward the mountain chain becomes suddenly depressed, especially its primitive rocks, the beds of gneiss and mica slate meeting as they advance with accumulations of secondary calcareous substances, which envelope them completely, and rise to a great elevation. The incumbent mass of sandstone, with a calcareous base, extending from Capelluari, forms a detached range of mountains in which no trace of primitive rock is found.

The *second* branch, which stretches from the Andes across the American continent, and exhibits a chain of primitive mountains, is named by Humboldt the *Cordillera of the Cataracts of Orinoco.* This very enterprising traveller surveyed it over an extent of upwards of 600 miles, from the Black River to the frontiers of the Great Bara; but the rest of the chain is very little known, running through unexplored wilds and regions almost inaccessible, occupied by fierce and independent tribes of savages. It leaves the great trunk between the 3d and 6th degree of southern latitude, and runs eastward from the *Paramo* or high desert of Tuquillo and St Martin, and the sources of the Guaviari, rearing the lofty summits of Umama and Canavami, and pouring forth the large rivers Meta, Zama, and Ymerida, which form the *roudals* or tremendous rapids of Aturé and Maypuré, the only openings existing at present between the interior of the continent and the plain of the Amazon. Beyond these cataracts the chain of mountains again acquires greater elevation and breadth, occupying the vast tract inclosed between the rivers Caura, Cavony, and Padamo, and stretching southward to the boundless forests where the Portuguese settlers gather that valuable drug the *sarsaparilla.* Farther eastward this chain is not traced, no European or civilised Indian having ever explored the sources of the Orinoco; all access in that quarter being prevented by the ferocity of the Guaicas, a dwarfish but very fair and warlike race, and by the valour of the Guajaribos, a most desperate tribe of cannibals. Beyond these recesses, however, we are made acquainted with the continuation of the chain of the cataracts, by the astonishing journey performed by Don Antonio Santos, who, disguised like a savage, his body naked, and his skin stained of a copper colour, and speaking fluently the several Indian dialects, penetrated from the mouth of the Rio Caroni to the Lake of Parimó and the Amazon. The range of mountains sinks lower, and contracts its breadth to 200 miles, where it assumes the name of Serrania de Quimeropaca and Pacaraimo. A few degrees farther eastward it spreads out again, and bends south to the Canno Pirara along the Mao, near whose banks appears the Cerro or hill of Ucucuamo, consisting entirely of a very shining and yellow mica slate, which has therefore procured from the credulity of early travellers the magnificent appellation of *Dorado* or Golden Mountain. East from the river Essequibo this Cordillera stretches to meet the granitic or gneiss mountains of Dutch and French Guiana, inhabited by confederated bands of negroes and Caribs, but giving birth to the commercial streams of Berbice, Surinam, and Corentin.

The chain of the cataracts of Orinoco has only a mean height of about 4000 feet above the level of the sea. The greatest elevation occurs where the mountain of Duida rears its enormous mass from the midst of a luxuriant plain, clothed with the tropical productions of palms and ananas, and discharges from its steep sides, about the close of the rainy season, volumes of incessant flames. No one has yet had the resolution or perseverance to climb through the tangling and rampant bushes to its peak, which, measured trigonometrically, gives an altitude of 8465 feet above the sea. The whole mountain group which forms this Cordillera is distinguished by the abrupt descent of its south flank; nor is it less remarkable for containing no rock of secondary formation, or exhibiting any vestige of petrifactions and organic remains. It contains only granite, gneiss, mica slate,

and hornblende, without any casing or admixture of sandstone or calcareous matter.

The *third* great branch sent out from the trunk of the Andes is that of the *Chiquitos*, which province it traverses, making a sort of semicircular sweep between the parallels of 15 and 20 degrees south latitude, and appearing to connect the colossal heights of Peru and Chili with the mountains of Brazil and Paraguay. It supplies the rivers that feed the Marañon on the one side, and the Plata on the other. The structure and disposition, however, of the Cordillera of the Chiquitos still remain almost unknown.

These grand chains of mountains divide the southern continent of America, from the latitude of 19 to that of 52 degrees, into three immense plains, which on the west side are shut up by the enormous ridge of the Andes, but are all open on the east, and towards the Atlantic Ocean. The most northern is the valley of the Orinoco, consisting of savannahs or level tracts covered with reedy herbage and scattered palms. The next is the plain of the Marañon, which is entirely covered with dense, impenetrable forests. The third and southernmost valley is the Pampas, a dead flat of most prodigious expanse, clothed, like that of the Orinoco, with a coarse, rank herbage, and abandoned to the occupation of countless herds of wild cattle.

Of these immense plains, the subsoil resembles the composition of the neighbouring mountains. In the valley of the Orinoco, the primitive rock is generally wrapt in a coat of sandstone, with calcareous cement, or covered with calcareous concretions, which betray the vestiges of recent organic remains, but show none of the older impressions, such as the belemnites and ammonites, so common in Europe. The woody plain of Marañon is distinguished by the thinness of its soil, and the total absence of any calcareous ingredients, the granite approaching close to the surface, which is in some places left quite bare over an extent of many furlongs. But the Pampas of Buenos Ayres are covered to a great depth with beds of alluvial deposits, in which the powers of vegetation, fomented by the rays of a burning sun, luxuriate in wanton profusion.

The lake of Titicaca covers a surface of 4000 square miles, being in some places 120 fathoms deep. It has an elevation of 12,795 feet above the sea, and terminates at the mountain Potosi, which rises to 16,000 feet, and is yet covered with the ruins of the ancient Peruvian civilisation. Near this centre the volcano of Arequipa stands, at the height of 18,373 feet, while the double peak of the *Nevados*, or snowy Illimani, tower to the enormous elevations of 24,200 and 24,450 feet, or about 3000 feet above the summit of Chimborazo, which was long regarded as the loftiest pinnacle of our globe. But, in the northern extension of the Cordillera, Sorata rears its snowy head, at the stupendous elevation of 25,200 feet, according to the observation of Pentland.

In those tropical regions cultivation ascends to very near the limits of perpetual snow. Various prolific crops, and particularly wheat and potatoes, are grown at the height of 14,000 feet above the level of the sea. A considerable population, dispersed in towns or villages, occupy tracts about 1000 feet higher, and enjoy health and vigour in a keen atmosphere, twice as rare as at the level of the sea. The ancient Peruvians had worked some gold mines at the vast altitude of 17,000 feet.

Humboldt has shown in his interesting essay, *Sur le Gisement des Roches*, the agreement of the geognostic arrangement of rocks in the Old and New Worlds. Granite appears in both regions the lowest discoverable material of our globe: to it succeeds the laminated species, or gneiss; then mica slate, containing garnets; next primitive slate, with beds of alum slate; now slate mixed with hornblende; above this, greenstone or primitive trap, followed by amygdaloid; and last of the series, porphyry slate. Resting or flanked against those primary rocks, beds of the older limestone begin to appear, with mica slate, hornblende, gypsum, and calcareous sandstone, followed by a suite of minerals bearing indications of organic remains. The only formations which Humboldt did not meet with in his extensive travels, were those of chalk, roestone, graywacke, topaz rock, and the compound of serpentine with granular limestone which occurs in Asia Minor. The grand ridge of the Andes is everywhere covered with porphyry, basalt, phonolite, and greenstone; which being often broken into columns, appear at a distance like ruined castles, and produce a very striking effect. Near the bottom of that enormous chain, two different sorts of limestone occur; one with a silicious base, inclosing sometimes cinnabar and coal; and another mostly calcareous, and cementing the secondary rocks. These formations are of enormous thickness and elevation. "Beds of coal are found in the neighbourhood of Santa Fé, 8650 feet above the level of the sea; and even at the height of 14,700, near Huanco in Peru. The plains of Bogota, although elevated 9000 feet, are covered with gypsum, sandstone, shell-limestone, and even in some parts with rock salt. Fossil shells, which in the Old continent have not been discovered higher than the summits of the Pyrenees, or 11,700 feet above the sea, were observed in Peru, near Micuipampa, at the height of 12,800 feet; and again at that of 14,120, beside Huancavelica, where sandstone also appears. The basalt of Pichincha, near the city of Quito, has an elevation of 15,500 feet, while the top of the Schneekoppe in Silesia—the highest point in Germany where that species of rock occurs, is only 4225 feet above the sea. On the other hand, granite, which in Europe crowns the loftiest mountains, is not found in the American continent above the height of 11,500 feet. It is scarcely known at all in the provinces of Quito and Peru. The frozen summits of Chimborazo, Cayambé, and Antisana, consist entirely of porphyry, which, on the flanks of the Andes, forms a mass of 10,000 or 12,000 feet in depth. The sandstone near Cuença has a thickness of 5000 feet, and the stupendous mass of pure quartz on the west of Caxamarca measures perpendicularly 9600 feet. It is likewise a remarkable fact, that the porphyry of those mountains very frequently contains hornblende, but never quartz, and seldom mica.

"The central Andes are rich beyond conception in all the metals, lead only excepted. One of the most curious ores in the bowels of those mountains is the *pacos*, a compound of clay, oxide of iron, and the muriate of silver with native silver. The mines of Mexico and Peru, so long the objects of envy and admiration, far from being yet exhausted, promise, under a liberal and improved system, to become more productive than ever. But nature has blended with those hidden treasures the active elements of destruction. The whole chain of the Andes is subject to the most terrible earthquakes. From Cotopaxi to the South Sea no fewer than forty volcanoes are constantly burning; some of them, especially the lower ones, ejecting lava, and others discharging the muriate of ammonia, scorified basalt, and porphyry, enormous quantities of water, and especially *moya*, or clay mixed with sulphur and carbonaceous matter. Eternal snow invests their sides, and forms a barrier to the animal and vegetable kingdoms. Near that confine the torpor of vegetation is marked by dreary wastes."—(*Edin. Review*, vol. xv. p. 233.)

We may subjoin that, near Quito, the liquid mud ejected by the volcanoes often involves myriads of small dead fish (*Pimelodes Cyclopum*), and, in some parts, the mountains, like the fabled cave of Æolus, seem at times to let out their imprisoned air, and produce such furious gusts of wind as to

sweep every thing before them to a vast distance. In other districts, the efforts of the contending elements are betrayed, especially during the rainy season, by a doleful moaning noise, or hollow and portentous groans, enough to cast a darker shade on the gloom of superstition, and to fill the imagination of the remotest settler with secret awe and dread.

A person who for the first time climbs the mountains of Switzerland is astonished to witness, in the space perhaps of a few hours, so rapid a change of climate, and such a wide range of vegetable productions. He may begin his ascent from the midst of warm vineyards, and pass through a succession of chesnuts, oaks, and beeches, till he gains the elevation of the hardy pines and stunted birches, or treads on Alpine pastures, extending to the border of perpetual snow. But within the tropics every thing is formed on a grander scale. The boundary of permanent congelation is 7500 feet higher at the equator than at the mean latitude of 45 degrees. Under a burning sun ananas and plantains grow profusely near the shore; oranges and limes occur a little higher; then succeed fields of maize and luxuriant wheat; and the traveller has actually reached the high plain of Mexico, or the still lofter vale of Quito, before he finds a climate analogous to that of Bordeaux or of Geneva. Now only commences the series of plants which inhabit the central parts of Europe.

But the very magnitude of the Andes appears to have the effect of diminishing the impressions of awe and wonder which the sight of them so powerfully excites. The country on which they rest is heaved to such a vast altitude above the sea, that the relative elevation of their summits becomes diminished in comparison with that of the surrounding amphitheatre. The majestic forms of Chimborazo, Cotopaxi, and Antisana, though 6000 feet higher than Mont Blanc, and clothed, like it, with eternal snow, seem to a traveller scarcely more sublime from the plains of Riobomba and Quito, than that celebrated mountain when viewed from the vale of Chamouni. It requires some time for his imagination to expand itself to the new scale of grandeur.

The central Andes, with all their magnificence, want a feature which, in the higher latitudes, contributes so much to the beauty and sublimity of the Alpine scenery. They have no vestige whatever of *glaciers*, those icy belts dropping from the limits of congelation, and spreading in concrete sheets, or hanging in disjointed columns fantastically thrown, which occur alike in the heart of Switzerland and on the northern shores of Norway and Lapland. This defect is evidently owing to the almost uniform temperature which prevails near the equator. In those torrid regions the days are constantly of the same length, and the sun shines through the whole year with very nearly equal force. The limit of perpetual congelation is hence marked on the sides of the mountains of Quito with singular precision. The temperature decreases regularly in proportion as one ascends them, till at a certain altitude it comes to the point of freezing, where the permanent field of snow begins to appear, defined with an almost unvarying border. But in the higher latitudes the sun remains during the summer so long above the horizon, and shines with such augmented force, that the heat of the atmosphere, and consequently of the surface of the ground, suffers a wide alteration in the different seasons. To the general investure of snow is therefore annexed every winter a zone of considerable breadth, which again softens and partly melts away during the continuance of the summer months. This alternate thawing and freezing occasions the production of glaciers, by converting successively the lower detached masses of snow in the precipitous flanks of the mountains, into a collection of broken and intermingled pillars of translucid ice.

For the same reason, the Andes, though torn by flaming volcanoes, and convulsed by frequent and terrible earthquakes, are exempt from those *avalanches* and *éboulements* which in Switzerland and other mountainous parts of Europe often bury the helpless traveller in a torrent of snow, and batter down whole villages by the sudden discharge of a shower of rocks. Under the equator the variation of temperature throughout the year is so small as not to disturb the solidity of the vast collections of snow; but on the flanks of the Alps or Pyrenees, as the heat of the summer increases, portions of the upper field of snow become loosened, and, sliding down, put other masses likewise in motion, till spreading wider, and gaining accelerated force, the whole tide precipitates itself to the plain, sweeping all before it. Such is the accident of an *avalanche;* but the occurrence of an *eboulement*, though less frequent, is more tremendous. When the alternation of frost and thaw detaches a mass of rock, it rolls down the side of the mountain with resistless fury, shivering into fragments and tearing everything opposed to it, overwhelming men, cattle, and houses, in one common heap of ruins.

But the Andes are distinguished from the chains of the European mountains by frightful *quebradas* or perpendicular rents, which form very narrow vales of immense depth, whose terrific walls, fringed below with luxuriant trees and shrubs, seem to lift their naked and barren heads to the distant skies. The noted crevices of Chota and Cutaco are nearly a mile deep, the former measuring 4950, and the latter 4300 feet, in a vertical descent. The task of crossing such tremendous gullies is often a work of infinite toil and extreme danger. In those mountainous countries travellers are accustomed to perform their journeys sitting in chairs fastened to the backs of men called *cargueros* or " carriers." These porters are mulattoes, and sometimes whites, of great bodily strength and activity, who will climb along the face of precipices, bearing loads of twelve and fourteen, or even eighteen stone. The *cargueros* lead a vagabond life, exposed to incredible fatigue, but recommended to them by its irregular course. Often do those wretched men toil over mountains for the space of eight or nine hours every day, till, like beasts of burthen, their backs become chafed and raw with the load. In this deplorable condition they are not unfrequently abandoned by unfeeling travellers, and left alone to sicken, pine, or die in the forests. Yet their earnings would appear inadequate to such violent and overpowering exertions, since they receive scarcely three guineas for performing the journey from Ibague to Cartago, which requires fifteen, and perhaps twenty-five or thirty days.

The Icononzo, remarkable for its natural bridges, is a small *quebrada* or cleft of the mountains, through which flows the river of the Summa Paz, descending from the highest upland desert. The rocks consist of two different kinds of sandstone, the one extremely compact, and the other of a slaty texture, divided into their horizontal strata. The rent was probably caused by an earthquake, which the harder portion of the stony mass had resisted, and now connects the upper part of the chasm. This natural arch is 50 feet long, 40 broad, and 8 feet thick at the middle. Its height is about 300 feet above the surface of the torrent, which has a medium depth of twenty feet. About 60 feet below the natural bridge another smaller arch occurs, composed of three slanting blocks of stone wedged together, which had probably fallen from the roof at the same instant of time, and struck against the sides of the crevice in their descent.

The natural bridge of Icononzo has perhaps no counterpart in the Old World; but the writer of this article had the pleasure of seeing, in early life, a similar phenomenon scarcely inferior to it in the United States of America. We allude to the famous arch described by Mr Jefferson, which crosses the Cedar creek in Rockbridge county, about a

hundred miles beyond the Blue Ridge, in the higher district of Virginia. The divided rock is a pure limestone, leaving a chasm about 90 feet wide, of which the walls are 230 feet high, sprinkled with verdant bushes, and enamelled with gay flowers, among which the *aquilegia* is conspicuous. This bridge, viewed from a little distance below, has all the appearance of a Gothic arch; and is of such solidity, that loaded waggons used formerly to pass along it, till a more convenient line of road was formed.

In some places the natives of Peru connect the clefts of their mountains by pendulous bridges thrown fearlessly across, and suspended from both sides of a gap. They are composed of ropes made of the tough fibres of the *agavé*, hanging in a gently sloping curve, and covered with reeds or canes, with occasionally a narrow border of basket-work. The intrepid Indian, regardless of the horrors of the unfathomed abyss which yawns from below, commits himself to his frail and floating arch, and swiftly glides along its bending curvature, till he gains the opposite bank.

The Andes likewise give rise to waterfalls of immense height and amazing force. The cataract of Tequendama, considered in all its circumstances, rivals any other in the known world. The basin which feeds its streams is the vast plain of Bogota, 7465 feet above the level of the sea, encircled completely with lofty mountains, except where the water, aided probably by the concussion of an earthquake, has cut for itself a narrow passage. The river Funcha, swelled by numerous feeders, gradually contracts its channel to the breadth of about 40 feet, and then gathering augmented force, dashes at two bounds from a perpendicular height of near 600 feet into a dark gulf. Owing to the excessive rapidity and depth of its current, it must discharge a prodigious volume of water, which quite stuns the ear by the roar of its crash; while it raises enormous clouds of thick spray and vapour, that continually bedew, and perhaps quicken, the vegetation of the adjacent grounds. Every thing conspires to exalt the beauty and grandeur of the scenery. "Independent of the height and mass of the column of water," says Humboldt, "the figure of the landscape, and the aspect of the rocks, it is the luxuriant form of the trees and herbaceous plants, their distribution into thickets, the contrast of those craggy precipices, and the freshness of vegetation, which stamp a peculiar character on these great scenes of nature." The transition from a temperate to a warm climate is rapid and surprising. The plain of Bogota bears rich crops of wheat, then succeed oaks and elms, intermingled with aralias, bigonias, and the yellow-bark trees; but immediately below the cataract a few palms appear, as if to mark the advance to a sultry soil.

A lively idea of the character and grand features of the Andes may be conceived from the account which the celebrated Humboldt has given of his journey across that majestic chain. Our readers will be glad to peruse it in the author's own words.

"The mountain of Quindiu, in the latitude of 4° 36′, is considered as the most difficult passage in the Cordilleras of the Andes. It is a thick uninhabited forest, which, in the finest season, cannot be traversed in less than ten or twelve days. Not even a hut is to be seen, nor can any means of subsistence be found. Travellers, at all times of the year, furnish themselves with a month's provision, since it often happens that, by the melting of the snows, and the sudden swell of the torrents, they find themselves so circumstanced that they can descend neither on the side of Cartago nor that of Ibague. The highest point of the road, the Garito del Paramo, is 11,500 feet above the level of the sea. As the foot of the mountain, towards the banks of the Cauca, is only 3150 feet, the climate there is generally mild and temperate. The pathway, which forms the passage of the Cordilleras, is only 12 or 15 inches in breadth, and has the appearance, in several places, of a gallery dug and left open to the sky. In this part of the Andes, as almost in every other, the rock is covered with a thick stratum of clay. The streamlets which flow down the mountains have hollowed out gullies about 20 feet deep. Along these crevices, which are full of mud, the traveller is forced to grope his passage, the darkness of which is increased by the thick vegetation that covers the opening above. The oxen, which are the beasts of burden commonly used in this country, can scarcely force their way through these galleries, some of which are more than a mile in length; and if perchance the traveller meet them in one of these passages, he finds no means of avoiding them but by turning back and climbing the earthen wall which borders the crevice, and keeping himself suspended by laying hold of the roots which penetrate to this depth from the surface of the ground.

"We traversed the mountain of Quindiu in the month of October 1801, on foot, followed by twelve oxen, which carried our collections and instruments, amidst a deluge of rain, to which we were exposed during the last three or four days, in our descent on the western side of the Cordilleras. The road passes through a country full of bogs, and covered with bamboos. Our shoes were so torn by the prickles which shoot out from the roots of these gigantic gramina, that we were forced, like all other travellers who dislike being carried on men's backs, to go barefooted. This circumstance, the continual humidity, the length of the passage, the muscular force required to tread in a thick and muddy clay, the necessity of fording deep torrents of icy water, render this journey extremely fatiguing; but, however painful, it is accompanied by none of those dangers with which the credulity of the people alarms travellers. The road is narrow, but the places where it skirts the precipices are very rare.

"When travellers reach Ibague, and prepare to cross the forests of Quindiu, they pluck, in the neighbouring mountains, several hundred leaves of the vijao, a plant of the family of the bananas, which forms a genus approaching to the Thalia, and which must not be confounded with the *Heliconia Bibai*. These leaves, which are membranous and silky, like those of the *Musa*, are of an oval form, two feet long and 16 inches broad. Their lower surface is a silvery white, and covered with a farinaceous substance, which falls off in scales. This peculiar varnish enables them to resist the rain during a long time. In gathering these leaves, an incision is made in the middle rib, which is the continuation of the foot stalk; and this serves as a hook to suspend them when the movable roof is formed. On taking it down, they are spread out, and carefully rolled up in a cylindrical bundle. It requires about an hundredweight of leaves to cover a hut large enough to hold six or eight persons. When the travellers reach a spot in the midst of the forests where the ground is dry, and where they propose to pass the night, the cargueros lop a few branches from the trees, with which they make a tent. In a few minutes this slight timber-work is divided into squares, by the stalks of some climbing plant, or the threads of the agavé placed in parallel lines 12 or 13 inches from each other. The vijao leaves meanwhile have been unrolled, and are now spread over the above work, so as to cover it like the tiles of a house. These huts, thus hastily built, are cool and and commodious. If, during the night, the traveller feels the rain, he points out the spot where it enters, and a leaf is sufficient to obviate the inconvenience. We passed several days in the valley of Boquia, under one of those leafy tents, which was perfectly dry amidst violent and incessant rains."

For further information relative to the structure of the Andes, see the various sketches given by Humboldt, and

particularly an abstract of his geological observations inserted in the *Journal de Physique*, vol. liii. for 1801. See likewise, by the same author, a memoir on the Geographic and Geognostic labours of M. Pentland, in the *Nouvelles Annales des Voyages et des Sciences Géographiques* for October, November, and December, 1829. (J. L.)

ANDES, the birth-place of Virgil, was a village in the vicinity of Mantua. The modern village of Pietola, about two miles from that city, is supposed to occupy its site.

ANDOCIDES, son of Leogoras, an Athenian orator and soldier, who was implicated with Alcibiades in the charge of mutilating the *Hermæ* of the city, and went into exile for a time. He returned to Athens when Thrasybulus restored liberty to his country. Four orations attributed to him remain; but the authenticity of the one against Alcibiades is disputed.—See Bekker's *Attic Orators*.

ANDORRE, or ANDORRA, *Republic of*, a small state of about 190 square miles in extent, occupying a valley on the Spanish side of the Pyrenees. It is a hilly district, with some good pasture for sheep, and several mines of iron, which are worked by the numerous rapid streams that pass through the district in their course towards Catalonia. It is divided into six parishes, viz., Andorra la Vieja, San-Julian-de-Loria, Encap, Canillo, Ordino, and Masana. Pop. in 1846, from 5000 to 6000. The capital is Andorra, the principal parish of the valley. The Andorrans are a robust and well-proportioned race, of an independent spirit, and simple and severe in their manners. All the inhabitants capable of bearing arms are reviewed once a year. Though each parish has a school, education has made little progress among them. They speak the Catalan language. Their religion is the Roman Catholic. This small state has preserved its independence since the time of Charlemagne, who, about the year 790, declared it a free state in reward for the services the inhabitants had rendered him in assisting his passage through the defiles of the mountains of Catalonia when he was marching against the Moors in Spain. Louis le Debonnaire ceded to the bishop of Urgel a part of the rights over Andorra which Charlemagne had reserved to himself and his successors; and in virtue of this right the bishop still exercises a spiritual jurisdiction over the country. In civil affairs its nominal protector is France, to which it pays an annual tribute of 960 francs for the privilege of importing from that country, free of duty, a stipulated quantity of certain specified articles, the produce of the country being insufficient for the wants of the inhabitants. The Andorrans manfully resisted the invasion of the Spaniards; and, during the wars of the Pyrenees, they rendered to France every assistance in their power. The government is composed of a supreme council of twenty-four members, of whom each parish elects four. The council chooses a syndic, whose office is for life, and who exercises the executive power. Justice is administered by two judges; one nominated by France, the other, who must be an Andorran, by the bishop of Urgel. The former is usually the justice of peace for the canton of Ax. The expenses of government are defrayed by a species of rent paid by owners of flocks to the community for the use of the pasture land.

ANDOVER, a market and borough town in the hundred of the same name, in Hampshire, on the river Anton, and 63 miles from London, on the great road to the west of England. It is well built, and has some trade in shags for silk hats, and in malt. The church is a spacious structure, and existed in the time of William the Conqueror. Andover was a Roman station, and remains of their encampments are still to be seen in the neighbourhood. It returns two members to parliament. A canal connects it with Southampton and the sea. Pop. in 1851, 5395.

ANDOVER, a town in the state of Massachusetts, United States, North America, 21 miles north of Boston, in a pleasant site, on the south banks of the river Merrimac. It has some manufactures; but is chiefly noted for its literary institutions, especially its theological seminary, which was founded in 1807. It has a president and four professors, and a library containing above 20,000 volumes. Tuition and apartments are free to all; and the very indigent receive further aid. There is also Philip's academy for the learned languages, which has a principal master, and three assistants. The number of pupils is limited to 130.

ANDRADA, DIEGO DE PAYVA D', or ANDRADIUS, a learned Portuguese, born at Coimbra in 1528, who distinguished himself at the council of Trent, where he was sent by King Sebastian as one of his divines. He wrote several volumes of sermons, and other pieces; one of which, *De Conciliorum Autoritate*, was highly esteemed at Rome on account of the great extension of authority which it gave to the pope. He died in 1575.

ANDRADA E SYLVA, BONIFACIO JOZÉ DE, a distinguished Brazilian naturalist and statesman, was born in 1765 and died in 1838. He took a prominent part in the Revolution of Brazil, and in 1831 was recalled from his banishment in France to accept the charge of the young emperor's education, but after two years, political hostility again drove him into retirement. His works consist chiefly of memoirs relative to mines.

ANDRÉ, JOHN. This accomplished and unfortunate man was born in London in 1751. Accident led him to Buxton in 1759, where he became acquainted with and deeply enamoured of Miss Honora Sneyd; but her friends disapproving of the match, induced her to discontinue her correspondence with him, and after some years persuaded her to give her hand to Mr Lovell Edgeworth. In the meantime, André, in the hope of improving his circumstances, had engaged in the service of a considerable mercantile house in London; but on the marriage of Miss Sneyd, he determined on abandoning his profession, and soon obtained a commission in a regiment destined for America, the theatre at that time of the war of Independence. In this new sphere, his talents and acquirements gained him rapid promotion, and in the year 1780 he was a major in the army, adjutant-general of the British forces in America, and aid-de-camp to General Sir Henry Clinton, their commander-in-chief.

When in this situation, the American general, Arnold, who had displayed much energy in the cause of the colonics, conceiving himself injuriously treated by his colleagues, made a proposition to the British to betray to them the important post of West-Point, the key of the American position. This seemed a favourable opportunity of concluding the war, and Major André was appointed to negotiate with Arnold. For this purpose he landed from a vessel bearing a flag of truce, and had an interview with Arnold; but before the negotiations were finished, an American fort had fired on the vessel, and forced her to drop down the river. André therefore could not return by the way he came, and it was necessary to go to New York by land: in the meantime, his guide brought him, without his knowledge, within the American lines, where he was provided with a plain dress instead of his British uniform, and a passport under the name of John Anderson, in which disguise he set out on horseback for headquarters. After passing the outposts undiscovered, he was stopped by three militiamen of the enemy and carried back a prisoner. Washington sent him before a court-martial, and notwithstanding a spirited defence, and the remonstrances of the British general, who did all he could to save him, Major André was executed at Tappan as a spy—a sentence perhaps justified by the extreme rigour of martial law, as he had been in disguise within the lines of the enemy; but the traitor Arnold,

through the address of poor André, escaped by timely flight the punishment he justly merited.

Besides courage, and distinguished military talents, Major André possessed a well-cultivated mind. He was a proficient in drawing and in music, and showed considerable poetic talent in his humourous *Cow-chase*, which appeared in three successive parts at New York; the last on the very day of his capture. One of his last letters gives an affecting incident relating to his first love. When stripped of everything by those who seized him, he contrived to retain the portrait of Honora, which he always carried on his person, by concealing it in his mouth. He was not aware that this lady had breathed her last some months before. A mural sculptured monument to the memory of Major André was erected in Westminster Abbey by the British Government, when his remains were brought over in 1821, and there interred. (T. S. T.)

ANDREA Del Sarto, see Vannuchi.

Andrea, *Giovanni*, a celebrated canonist, born (says Tiraboschi) at Bologna, towards the end of the thirteenth century, of parents who were natives of Mugello near Florence. His father kept a grammar school at Bologna; but eight years after the birth of his son, having obtained the living of Sta Maria de' Galluzzi, he took orders, and rebuilt that church at his own expense. Andrea studied civil law under Martino Sulimans and Ricardo Malombra, and canon law under Guido da Baijo. The words *Sub cujus umbra quiesco, et doctor sedeo*, in the beginning of his Decretals, are supposed to have reference, not as commonly asserted to pecuniary assistance from Baijo, but to the professorship which through his interest Andrea obtained at Bologna, whither he removed from Padua where he had previously kept a school. In 1328 he was introduced by Cardinal Bertrando to Pope John XXII. at Avignon. Four years afterwards, when popular fury obliged the cardinal to leave Bologna, Andrea accompanied him to Florence, where he cannot have remained long, for in 1337 he was sent from Bologna on an embassy to Venice and Padua. He was a member of the general council of Bologna in 1340; and if he ever was professor at Pisa, as commonly supposed, it was probably after that period, as no mention of him occurs again until 1348, when it is recorded that he died at Bologna of the plague, and was buried in the church of the Dominicans. The aspersions on the character of this eminent man, must be ascribed to the malevolence of those who envied his great reputation: the titles of *rabbi doctorum, lux, normaque morum*, bestowed on him, prove the public estimation of his learning, and his morals; and R. Volterrano and Filippo Villani testify to his vigils, fasting, and mortification. The story that his accomplished daughter Novella occasionally supplied her father's place in the lecture room, concealed by a curtain lest her beauty should distract the attention of the pupils, appears to rest on very slender foundation; and equally improbable is the common opinion that he named the decretals of Gregory "Novella" in honour of her, that title having probably been given after the example of Justinian in his supplement to the Corpus Juris. Andrea wrote the following works:—*Gloss upon the Sixth Book of the Decretals; Glosses upon the Clementines; Commentary on the Rules of Sextus.* His additions to the *Speculum* of Durando, are taken literally from the *Consilia* of Oldradus; as also the book *De Sponsalibus et Matrimonio* from J. Anguisciola.

Andréa, *Giovanni*, bishop of Aleria in Corsica, a descendant of the family of Bussi or Bossi, was born at Vigevano in 1417. He is celebrated in literary history as having been highly instrumental in introducing printing into Rome, and as the editor of the first editions of several classical authors printed in that city by Sweyheim and Pannartz. The merit of Andréa was the greater, that in early life he had to contend against the disadvantages of extreme poverty. He died in 1475.—Trithemius, *De Script. Eccles.*

Andrea of Pisa. See Pisano.

ANDREÆ, Johann, archivist to the counts of Nassau, about the commencement of the seventeenth century. His voluminous history of that house, which is preserved in MS. in the Walram archives, contains citations from many curious historical documents that were afterwards lost during the thirty years' war.

ANDREANI, Andrea, a celebrated engraver on wood, in chiaroscuro, born at Mantua about 1540. He brought the art to great perfection. His outline is fine, and with a few touches he gives great expression to the heads. His largest work is the *Triumph of Cæsar*, after the cartoons of Andrea Mantegna, now at Hampton Court: perhaps his masterpiece is *Christ retiring from the judgment-seat of Pilate*, in which the Roman Governor is represented as washing his hands. He died at Rome in 1623.

ANDREAS, or Andre, St, a market-town on the Danube, in the circle of Pilesch, and palatinate of Pesth, in Hungary. It contains one Roman Catholic and seven Greek churches, 1040 houses, and 7980 inhabitants, who trade very extensively in the wine produced in the vicinity. In the Danube, opposite to the town, is an island of the same name, which is fourteen miles in length and one in breadth, and remarkable for its fertility.

ANDREASBERG, the capital of the bailiwick of the same name, in the principality of Grubenhagen, kingdom of Hanover. It is 1915 feet above the level of the sea, on the declivity of the Hartz mountains, and contains 4400 inhabitants, who subsist chiefly by mining, the females being employed in making lace. In its vicinity are mines of iron, cobalt, copper, and silver. Lat. 51. 43. N. Long. 10. 31. E.

ANDREINI, Giovanni Battista, born about 1578, was the son of Francesco and Isabella Andreini, both highly celebrated on the Italian stage towards the close of the sixteenth century. Their son is only noticed here as having been the author of a sacred drama, entitled *Adamo*, which was supposed by Voltaire to have suggested to Milton the outline of his *Paradise Lost*, though the original has in reality so little merit that Ginguene sarcastically observes —"*C'est faire trop d'honneur à un tel ouvrage.*"

ANDRELINI, Publio Fausto, born at Forli in Italy. He was a long time professor of poetry and philosophy in the university of Paris. Louis XII. of France made him his poet laureate, and Erasmus tells us that he was likewise poet to the queen. His pen was not wholly employed in making verses, for he wrote also moral and proverbial letters in prose, which were printed several times. Some of his poems, which are chiefly in Latin, are inserted in vol. i. of the *Deliciæ Poetarum Italorum.* He died in 1518.

ANDREOSSY, Antoine-François Comte d', a very distinguished officer of artillery in the service of France, was born in Languedoc in 1761. His family had originally been Italian. He early joined the revolutionary party, was a lieutenant of artillery, and served with distinction in Italy and in Egypt under Buonaparte. In Egypt, he was an active member of the Institute of Cairo, in whose Transactions are several of his memoirs, especially on *The Valley of the Natron Lakes*, and on *The Lake Menzaleh.* He was selected by Buonaparte as one of his companions on his unexpected return to Europe; and served with approbation in his subsequent campaigns. Andreossy was appointed ambassador to London during the short peace of Amiens. When Napoleon assumed the title of Emperor, Andreossy was advanced to be inspector-general of artillery, and to the title of Count of the empire. After various military services, he was appointed ambassador to Austria, where he remained until the rupture with France in 1809; and when the fatal battle

of Wagram prostrated Austria, he became the temporary governor of Vienna. He was long Napoleon's representative at Constantinople, where he acquired the good opinion of Franks and Mahometans. In 1814 he was recalled by Louis XVIII., who sent him, however, the decoration of St Louis. Andreossy then retired into private life, till the escape of his former master from Elba once more drew him forth. After the decisive battle of Waterloo he wholly withdrew from public life, and amused his retirement with preparing for publication different memoirs on scientific subjects, especially his excellent work *Sur le Bosphore de Thrace, comprenant le systeme des eaux qui abreuvent Constantinople*, 8vo, 1818.

His *Histoire du Canal de midi ou de Languedoc* is interesting; but having claimed for his ancestor François Andreossy the principal merit of this undertaking, he was involved in a controversy with the descendants of the engineer Riquet, to whom it has been generally attributed. The decision of the best judges, however, had pronounced in favour of the latter. Andreossy died at Montauban in September 1828. (T. S. T.)

ANDRES, Juan (1740–1817), a native of Valencia. He is the author of a work entitled *Dell' Origine, dei Progressi e dello Stato Attuale d'Ogni Letteratura*, in 7 volumes 4to, the labour of upwards of twenty years, and full of erudition. It has passed through several editions. A just estimate of its merits will be found in Hallam's *Introduction to the Literature of Europe*, vol. i., and in Sismondi's *Literature of the South of Europe* (by Roscoe 1843), vol. i., p. 12, note.

ANDREW, St, the apostle, born at Bethsaida in Galilee, brother to Simon Peter. He had been a disciple of John the Baptist, and followed Jesus upon the testimony given of him by the Baptist. (John i. 35, 40, &c.) He was the first person whom our Saviour received as his disciple. Andrew introduced his brother Simon, and they passed a day with Christ, after which they went to the marriage in Cana (*ibid.* ii.), and at last returned to their ordinary occupation. Some months after, Jesus meeting them while they were both fishing together, called them to him, and promised to make them fishers of men. Immediately they left their nets, followed him (Matt. iv. 19), and never afterwards separated from him. Tradition assigns Scythia, Greece, and Thrace, as the scenes of St Andrew's ministry: he is said to have suffered crucifixion at Patræ in Achaia, on a cross of the form called *Crux decussata* (×), and commonly known as "St Andrew's cross." His relics, it is said, were afterwards removed from Patræ to Constantinople. An apocryphal book, bearing the title of *The Acts of Andrew*, is mentioned by Eusebius, Epiphanius, and others. It is now completely lost, and seems never to have been received except by some heretical sects, as the Encratites, Origenians, &c. This book, as well as a *Gospel of St Andrew*, was declared apocryphal by a decree of Pope Gelasius (Jones *On the Canon*, vol. i. p. 179, *et seq.*)

Andrew, or *Knights of St Andrew*, an order of knights, more usually called the Order of the Thistle.

Knights of St Andrew is also an order instituted by Peter the Czar of Muscovy in 1698, the badge of which is a golden medal, on one side whereof is represented St Andrew's cross, with these words, *Czar Pierre, monarque de toute la Russie.* This medal being fastened to a blue ribbon, is suspended from the right shoulder.

St Andrew's Day, a festival among certain religious denominations, celebrated on the 30th of November in honour of the apostle St Andrew.

ANDREWS, St, a city of Scotland, in the county of Fife, pleasantly situated on a rocky promontory, nearly fifty feet above the level of the sea, in a spacious bay of the German Ocean, into which flow the river Eden, the small rivulet of Kinness, and several other streams. It was formerly a place of much greater extent and importance. At present it is about a mile and a half in circuit, and consists of three leading streets, intersected by a considerable number of smaller streets and lanes. The principal street is well built, is straight and broad, and of late years its appearance, as well as that of the city generally, has been much improved. Several new streets and terraces have been recently formed towards the west, and many elegant and commodious houses erected. The streets are either substantially paved or macadamised, and are furnished throughout with foot-pavement of a superior description; so that, perhaps, no town in Scotland presents a neater or more cleanly appearance. The view of the city, with its many towers and turrets, from the rising ground on the south, or from the level plain on the west, is highly beautiful and picturesque. St Andrews is now much frequented as a summer residence, the principal attractions, in addition to its salubrious air and pleasant walks, being sea-bathing, and the favourite game of golf, of which it may be considered the headquarters in Scotland. The baths have been lately enlarged and greatly improved, and afford every accommodation for cold and warm bathing. St Andrews contains many interesting memorials of antiquity. Of the splendid cathedral, which was founded by Bishop Arnold in 1159, and attained to its highest magnificence in 1318, parts of the east and west ends, and of the south side, are all that now remain. The length of this edifice from east to west was 358 feet within the walls; that of the transept 180 feet. This whole pile of building, which it took 160 years to complete, was in June 1559 demolished in a single day by the iconoclastic fury of the Reformers. About 40 yards to the south-east is the chapel of St Regulus, the tower of which is a lofty square prism, the side of the base being 20 feet, and the height 108. The walls of the chapel to the east of the tower, which was the principal one, still remain; but of a small chapel to the west, which appears to have formerly existed, there is now no trace. The arches of the windows and doors are round, and the figure of some of them is more than half of the circle, which is an undoubted proof of their antiquity. The history of this ancient structure, which was undoubtedly a place of Culdee worship, is involved in great obscurity. The majority of antiquaries assign its erection to a date prior to the ninth century, while some carry it back to the latter part of the fourth century.

The Priory, which was founded by Robert, bishop of St Andrews, during the reign of Alexander I. in 1120, was of great extent, and richly endowed. The prior had precedence of all abbots and priors, and on festival days had a right to wear a mitre and all episcopal ornaments. The wall of the precinct is all that now remains to mark the vast extent of this edifice. This magnificent wall, which surrounded the cathedral and adjacent ecclesiastical edifices, was built by Prior John Hepburn, and was begun about 1516. It is nearly a mile in circuit, about 20 feet in height, and about 4 in breadth.

Part of the top of the great altar towards the east end of the cathedral was discovered half a century ago, in consequence of an excavation made in the hope of finding concealed treasure. At a much more recent period, the soil, which had for ages been permitted to accumulate, having been removed, part of the pavement was laid open, and several shafts of two rows of pillars parallel to each other, by which it is supposed that galleries in the inside of the walls had been supported. The other religious houses were, that of the Dominicans, founded in 1274 by Bishop Wishart; another of Observantines, founded by Bishop Kennedy, and finished by his successor Patrick Graham in 1478; and, according to some, the Carmelites had a fourth. Immediately

St Andrews. above the harbour stood the collegiate church of Kirkheugh, originally founded by Constantine III., who, retiring from the world, became here a Culdee. From its having been first built on a rock, it was styled *Ecclesia Sanctæ Mariæ de Rupe.*

On the north-east side of the city are the remains of the castle, on a rock overlooking the sea. This fortress was founded about the year 1200, by Roger, one of the bishops of St Andrews, and was repaired towards the end of the fourteenth century by Bishop Trail, who died in it in 1401. He was buried near the high altar of the cathedral, with this singular epitaph:

> Hic fuit ecclesiæ directa columna, fenestra
> Lucida, thuribulum redolens, campana sonora.

The castle was the residence of Cardinal Beaton, who, after the cruel execution of the celebrated reformer George Wishart in front of it, was afraid of the fury of the people; and his knowledge of this, joined to his apprehension of an invasion from England, induced him to strengthen the fortifications, with a view of rendering the castle impregnable. In this fortress he was surprised and assassinated by Norman Lesley, aided by fifteen others. Early in the morning of May 29. 1546, they seized on the gate of the castle, which had been left open for the workmen who were finishing the fortifications; and having placed sentinels at the door of the cardinal's apartment, they awakened his numerous domestics one by one, and, turning them out of the castle, without violence, tumult, or injury to any other person, inflicted on Beaton the death he justly merited. The conspirators were immediately besieged in this castle by the regent, Earl of Arran; and although their strength consisted of only 150 men, they resisted his efforts for five months, owing more to the unskilfulness of the attack than the strength of the place; for in 1547 the castle was reduced and demolished, and its picturesque ruins serve as a landmark to mariners. The entrance to the castle, and the window out of which it is said Cardinal Beaton leaned to witness the cruel martyrdom of George Wishart, are still pointed out.

The parish church, situated in South Street, is a spacious structure, 162 feet in length by 63 in breadth, and is large enough to accommodate 2500 persons. It contains a lofty monument of white and black marble, erected in honour of Archbishop Sharpe, who, in revenge for his oppressive conduct, was murdered by some of the exasperated reformers of that day. On this monument is a piece of sculpture representing the tragical scene of the murder. In North Street stands the college church, which belongs to the united college of St Salvator and St Leonard. It was founded in 1458 by Bishop Kennedy, and contains a beautiful tomb of its founder, who died in 1466; which is a fine specimen of the Gothic architecture of that period. About the year 1683, on opening this tomb, six highly ornamented silver maces were discovered, which had been concealed there in times of trouble; three of which are still preserved in the university, and three were sent to the other universities of Scotland. On the top of one of them is represented our Saviour; around are angels with the instruments of his passion.

St Mary's church, also connected with the Establishment, was erected in 1839. It is a plain but neat building, and seated for about 630 persons.

The Episcopal chapel, the Free church, and the United Presbyterian church, are situated in North Street, and are elegant and commodious structures. The Congregationalists and Baptists have also places of worship in the city.

In the United College are shown some silver arrows, with large silver plates affixed to them, on which are inscribed the arms and names of those who were victorious in the annual competitions of archery, which were regularly held until within these few years. Golf is now the reigning game. That sport, and foot-ball, were formerly prohibited by an act of parliament passed in the reign of James II. in 1457, as interfering too much with the acquisition of dexterity in archery, an accomplishment in those days of much consequence to the safety of the state. The statute has been long obsolete, and the inhabitants, and the students who attend the university, have full permission to enjoy this elegant amusement. St Andrews.

The celebrated university of this city was founded in 1411 by Bishop Wardlaw. It consisted formerly of three colleges. 1. St Salvator's was founded in 1458 by Bishop Kennedy. This was a handsome building, with a court or quadrangle, 230 feet long by 150 wide, and a gateway surmounted by a spire 156 feet high. On one side was the church; on another the library; the third contained apartments for students; the fourth was unfinished. 2. St Leonard's College was founded by Prior Hepburn in 1512. This is now united with the last, and the buildings have been sold, and converted into private houses. 3. New or St Mary's College was established by Archbishop Hamilton in 1552. This is said to have been the site of a celebrated school long before the establishment even of the University, where several eminent clergymen taught gratis the sciences and languages; but it was called the *New College*, because of its late erection into a college by the archbishop. The buildings of this college have been substantially repaired, and with great taste.

The United College was constituted in 1747 by the union of St Leonard's and St Salvator's, and occupies the site of the latter. The buildings connected with this college being in a state of great decay, a grant was made by government for erecting a new structure, which is now completed, and is in a high degree elegant and commodious. It is beautifully situated, overlooking the bay of St Andrews and the opposite coast of Angusshire, with the Sidlaw and Grampian hills in the distant north. It is enclosed on three sides by a high wall, and on the south by the College chapel. In front is a spacious area or quadrangle, 215 feet long by 160 feet wide, and behind is a garden neatly laid out in walks and planted with suitable shrubs. A cloister has been erected on the north side of the chapel, as a place of shelter and retirement for the students. Besides ample accommodation for the various classes, the new structure contains a large hall for general meetings of the students, and other academic purposes, and a Museum of Natural History and Antiquities. This museum is connected with the St Andrews Literary and Philosophical Society, which took its rise in 1838, and is principally composed of the professors of the University, and gentlemen resident in the city, who take an interest in the advancement of literature and science. There is also a valuable Anatomical Museum in the College.

The university, which is composed of the members of the United College and St Mary's College, is governed by a chancellor,—an office which it was originally intended should be permanently exercised by the Archbishop of St Andrews. Subsequent to the Revolution, the chancellor has been elected by the two principals and the professors of both colleges.

The rector is the next great officer, to whose care are committed the privileges, discipline, and statutes of the university. The colleges have their principals, and professors of different sciences, who are indefatigable in their attention to the instruction and the morals of the students. The place possesses, in its retired situation, its pure and salubrious air, its extensive grounds for exercise, and its excellent and cheap accommodation for students, very great advantages for the education of youth. In the United Col-

St Andrews.

lege are taught the languages, philosophy, and the sciences. St Mary's, which stands in a different part of the town, is reserved exclusively for theology. The classes and discipline of the two colleges are quite distinct, each having its respective principal and professors. They have a common library, containing nearly 60,000 volumes, and which was formerly entitled to a copy of all new books entered in Stationers' Hall; but, by an act of parliament passed in the year 1837, that right was abolished, and in lieu of it the library receives from the treasury the sum of L.630 annually for the purchase of books. By judicious management it is believed that this arrangement will prove more beneficial to the institution than the privilege it formerly enjoyed.

Eighty-six bursaries or endowments belong to the university, and are conferred on the students. Of these 65 belong to the United, and 21 to the New College. The foundation bursaries in the United College, 20 in number, are disposed of by comparative trial; the remaining bursaries are at the disposal of private patrons.

The Madras College was established in the year 1833, by the late Dr Andrew Bell, a native of St Andrews, and inventor of the monitorial system of education which bears his name, who bequeathed the munificent sum of L.50,000, in three per cent. stock, for its establishment. The building stands on the site of the Blackfriars' monastery. The system of education pursued comprises the classics, the English and other modern languages, writing, arithmetic, mathematics, and drawing. The fees being low, and in many cases not exacted, the institution has been very successful, the number of scholars averaging of late years about a thousand. Dr Bell also left a fund, which yields an annual revenue of upwards of L.300, to be expended on permanent improvements of the city, and educational and religious purposes.

The trade of St Andrews was once very considerable. So late as the reign of Charles I. it had thirty or forty trading vessels, and carried on a considerable herring and white fishery, by means of busses, in deep water, which had for ages been a most profitable branch of commerce, and a source of wealth. During the troubles which followed the death of this monarch, this whole coast, and St Andrews in particular, became a scene of murder and rapine; and every town suffered in proportion to its magnitude and opulence. St Andrews was required to pay a contribution of L.1000, which the inhabitants, after being plundered, were not able to raise: a composition of L.500 was accepted, which was raised by a loan at interest, and has remained a burden upon the corporation, it is believed, ever since.

The harbour of St Andrews is artificial, and is guarded by piers. It has been greatly improved within these few years, and is now pretty safe and commodious; but it is difficult of access, having a narrow entrance, and being exposed to the east winds, which raise a heavy sea on the coast. There is a light on the pier-head, showing green to the west, red to the south-east, and white to the north-east. A turret-light has also been recently erected on the north wall of the cathedral, which, from its elevated position, is of great service to vessels approaching the harbour at night. The shore of the bay is low; and, in the storms of winter, vessels are liable to be driven on it and lost.

St Andrews had a manufactory of sail-cloth to some extent, but it is now discontinued. The game of golf being much practised here, there is a manufactory of golf-balls, which, after supplying the home consumption, used to send about 9000 annually to other parts; but the recent introduction of gutta-percha balls has greatly diminished this source of industry. The shipping of the port consists of a few vessels, which are employed in the coasting trade. St Andrews is a royal burgh, and unites with Cupar, Easter and Wester Anstruther, Pittenweem, Crail, and Kilrenny, in returning a member to parliament. The town-council consists of 29 members, including the provost and four bailies. The number of registered voters in 1853 was upwards of 237, and the amount of poor-rates L.1290.

Andrews.

According to early traditions, St Andrews owes its origin to a Greek monk, Regulus, who, having been warned in a vision to visit Albion, was shipwrecked in the bay about the end of the fourth century. He was hospitably received by the king, who eventually was influenced to establish here the first Christian priests of the country, called *Culdees*. He also directed that the cross of St Andrew should become the badge of the country. In 818, after the conquest of the Picts, he removed the episcopal see to St Andrews, and the bishop was styled *maximus Scotorum episcopus*. In 1474 it was erected into an archbishopric by Sextus IV. at the intercession of James III. In 1606 the priory was suppressed; and in 1617 the power of election was transferred to eight bishops, the principal of St Leonard's College, the archdeacon, the vicars of St Andrews, Leuchars, and Cupar. This see contained the greater part of Fife, with a part of the counties of Perth, Forfar, and Kincardine, and a great number of parishes, churches, and chapels in other dioceses.

The town of St Andrews was erected into a royal burgh by David I. in the year 1140, and its privileges afterwards confirmed. The charter of Malcolm IV., written on a small bit of parchment, is preserved in the tolbooth. Here also are kept the silver keys of the city, which, according to traditionary usage, are to be delivered up to the sovereign on occasion of a royal visit. In this place, likewise, is to be seen the enormous axe with which, in 1646, Sir Robert Spotswood and other distinguished loyalists were beheaded. The town underwent a siege in 1337, at which time it was possessed by the English and other partisans of Baliol; but the loyalists, under the Earls of March and Fife, made themselves masters of it in three weeks, by the help of their battering machines.

St Andrews is nine miles east of Cupar, and 39 N.N.E. of Edinburgh, and is connected with the Edinburgh, Perth, and Dundee railway by a branch line to Leuchars. The population of the parliamentary burgh, according to the census of 1851, was 5084; and of the parish 6716. Long. 2. 50. W. Lat. 56. 19. 33. N. *The History of St Andrews*, by the Rev. C. J. Lyon, contains a detailed account of the city, of its ecclesiastical antiquities, and of the university. (W. P.)

Andrews, *James Pettit*, an English historian and miscellaneous writer, was the younger son of Joseph Andrews, Esq. of Shaw-house, near Newbury, Berks, where he was born in the year 1737. He was educated privately, and is said to have discovered an early taste for literature and the fine arts.

The most extensive work undertaken by Mr Andrews was his *History of Great Britain, connected with the Chronology of Europe; with Notes*, &c. The first volume, which commences with Cæsar's invasion, and ends with the deposition and death of Richard II., was published in 1794, in 4to. A second volume, in which the history is continued from the deposition and death of Richard II. to the accession of Edward VI., appeared in 1795. The plan of this work is new, and in some respects singular; a certain portion of the history of England is given on one page, and a corresponding portion of the contemporaneous history of Europe on the one opposite. The notes consist of a variety of curious and amusing particulars, not immediately connected with the main story. Appendixes are also added at proper intervals, containing an account of the state of literature, science, religion, government, manners, &c., at different periods. The author, however, did not live to complete

this curious and extensive work, no more of it having appeared than the two volumes above mentioned. In 1796 he published a continuation of Henry's *History of Britain*, in one volume 4to and two volumes 8vo, and died at Brompton the following year. He was the author of various other miscellaneous works.

Andrews, *Lancelot*, bishop of Winchester, was born at London in 1555, and educated at Cambridge. After several preferments he was made bishop, first of Chichester, then of Ely, and in 1618 was raised to the see of Winchester. This very learned prelate, who was distinguished by his piety, charity, and integrity, may be justly ranked with the best preachers and scholars of his age. He appeared, however, to much greater advantage in the pulpit than he does now in his works, which abound with Latin quotations and trivial witticisms. He died at Winchester house in Southwark, September 25. 1626, on the anniversary of his birth, and was buried in the parish church of St Saviour's, where his executors erected to him a handsome monument of marble and alabaster, with an elegant inscription in Latin, written by one of his chaplains. His most popular works are his *Sermons*, his *Lectures on the Ten Commandments*, and his *Orphan Lectures*, each forming a folio volume. There is a collection by Felix Kyngston of some other pieces written by him, which was published in 4to in 1629.

ANDRIA, a city and a bishop's see in the territory of Bari, kingdom of Naples, situated in a spacious plain, four miles from the Adriatic. It has a fine cathedral, and a royal college. Pop. 14,600. It derives its name from the caverns in its vicinity. Long. 16. 17. E. Lat. 41. 14. N.

ANDRIANTES, in *Grecian Antiquity*, statues erected in honour of the victors at the public games, a custom which appears to date from the 58th Olympiad. (Paus. vi. 18, § 5.) According to Pliny, it was necessary to have been thrice a victor, to be honoured with a *statua iconica*, or actual likeness. (*Hist. Nat.* xxxiv. 9.)

ANDRIEU, Bertrand, a celebrated engraver of medals, born in 1765 at Bordeaux, where his father was a vintner. He is considered as the restorer of the art in France, which had declined after the time of Louis XIV.; and was so highly esteemed, that during the last twenty years of his life he was entrusted by the French government with the execution of every work of importance. Many of his medals are figured in the *Medallic History of Napoleon.* He died in 1822.

ANDRISCUS, a man of mean extraction, who, pretending to be the son of Perseus, last king of Macedonia, took upon him the name of *Philip*, for which reason he was called *Pseudo-Philippus*, the *False Philip.* After a complete victory over Juventius, the Roman prætor, who was sent against him, he assumed kingly power, but exercised it with great cruelty. At last the Romans obliged him to fly into Thrace, where he was betrayed and delivered into the hands of Metellus, B.C. 148. This victory placed Macedonia once more in the power of the Romans, and gained for Metellus the name of Macedonicus, but cost the Romans 25,000 men. Andriscus adorned the triumph of Metellus, walking in chains before the general's chariot.

ANDROCLUS, a Roman slave who used to lead about the streets a lion which had forborne to injure him when turned loose in the circus. The story is related, on the authority of an eye-witness, by Aulus Gellius (v. 14), who states that Androclus had taken refuge from the severities of his master in a cave in Africa, and that while there, a lion entered the cave and presented to him his swollen paw, from which Androclus extracted a large thorn.

ANDROGEOS, in *Fabulous History*, the son of Minos, king of Crete, was murdered by the Athenian youth and those of Megara, who envied his being always victor at the Attic games. But Minos having taken Athens and Megara, obliged the inhabitants to send him an annual tribute of seven young men and as many virgins, to be devoured by the Minotaur. From this tribute they were delivered by Theseus.

ANDROIDES (ἀνήρ and εἶδος), a human figure, which, by certain springs or other movements, is capable of performing some of the natural motions of a living man. The motions of the human body are more complicated, and consequently more difficult to be imitated, than those of any other creature; whence the construction of an *androides*, in such a manner as to imitate any of these actions with tolerable exactness, is justly supposed to indicate a greater skill in mechanics than any other piece of workmanship whatever.

A very remarkable figure of this kind appeared in Paris in the year 1738. It represented a flute-player, and was capable of performing different pieces of music on the German flute; which, considering the difficulty of blowing that instrument, the different contractions of the lips necessary to produce the distinctions between the high and low notes, and the complicated motions of the fingers, must appear truly wonderful.

This machine was the invention of M. Vaucanson, member of the Royal Academy of Sciences; and a particular description of it was published in the Memoirs of the Academy for that year.

The figure itself was about 5½ feet in height, situated at the end of an artificial rock, and placed upon a square pedestal 4½ feet high and 3½ broad. The air entered the body by three pipes separated one from the other. It was conveyed to them by nine pairs of bellows, three of which were placed above and six below. These were made to expand and contract regularly in succession by means of an axis of steel turned round by some clockwork. On this axis were different protuberances at proper distances, to which were fixed cords thrown over pulleys, and terminating in the upper boards of the bellows, so that, as the axis turned, these boards were alternately raised and let down. A contrivance was also used to prevent the disagreeable hissing fluttering noise usually attending the motion of bellows. This was by making the cord by which the bellows was moved press, in its descent, upon one end of a smaller lever, the other end of which ascending, forced open the small leathern valve that admitted the air, and kept it so till, the cord being relaxed by the descent of the upper board, the lever fell, and the air was forced out. Thus the bellows performed their functions constantly without the least hissing, or other noise by which it could be judged in what manner the air was conveyed to the machine. The upper boards of three of the pairs of bellows, were pressed down by a weight of 4 lb., those of three others by a weight of 2 lb., and those of the three remaining ones by nothing but their own weight.

The three tubes by which the air entered terminated in three small reservoirs in the trunk of the figure. There they united, and, ascending towards the throat, formed the cavity of the mouth, which terminated in two small lips adapted in some measure to perform their proper functions. Within this cavity also was a small movable tongue, which, by its play, at proper periods admitted the air, or intercepted its passage to the flute.

The fingers, lips, and tongue, received their proper directions by means of a steel cylinder turned by clockwork. It was divided into 15 equal parts, which, by means of pegs pressing upon the ends of 15 different levers, caused the other extremities to ascend. Seven of these levers directed the fingers, having wires and chains affixed to their ascending extremities, which being attached to the fingers, caused them to ascend in proportion as the other extremity was

pressed down by the motion of the cylinder, and *vice versa.* Thus the ascent or descent of one end of a lever produced a similar ascent or descent in the corresponding finger, by which one of the holes of the flute was occasionally opened or stopped, as by a living performer. Three of the levers served to regulate the ingress of the air, being contrived so as to open and shut, by means of valves, the three reservoirs of air above mentioned, so that more or less strength might be given, and a higher or lower note produced as occasion required. The lips were, by a similar mechanism, directed by four levers, one of which opened them, to give the air a freer passage; the other contracted them; the third drew them backward; and the fourth pushed them forward. The lips were projected upon that part of the flute which receives the air; and, by the different motions already mentioned, modified the tone in a proper manner. The remaining lever was employed in the direction of the tongue, which it easily moved so as to shut or open the mouth of the flute.

Thus we see how all the motions necessary for a flute-player could be performed by this machine; but a considerable difficulty still remains, namely, how to regulate these motions properly, and make each of them follow in just succession. This, however, was effected by the following simple method: the extremity of the axis of the cylinder was terminated on the right side by an endless screw, consisting of twelve threads, each placed at the distance of a line and a half from the other. Above this screw was fixed a piece of copper, and in it a steel pivot, which, falling in between the threads of the screw, obliged the cylinder to follow the threads, and instead of turning directly round, it was continually pushed to one side. Hence, if a lever were moved by a peg placed on the cylinder in any one revolution, it could not be moved by the same peg in the succeeding revolution, because the peg would be moved a line and a half beyond it by the lateral motion of the cylinder. Thus, by an artificial disposition of those pegs in different parts of the cylinder, the statue was made, by the successive elevation and depression of the proper levers, to exhibit all the different motions of a flute-player, to the admiration of every one who saw it.

The construction of machines capable of imitating even the mechanical actions of the human body shows exquisite skill; but what shall we say of one capable, not only of imitating actions of this kind, but of acting as external circumstances require, as though it were endued with life and reason? This was supposed to have been accomplished by M. de Kempelen of Presburg in Hungary, who constructed an androides capable of playing at chess! Every one who is in the least acquainted with this game must know that it is so far from being mechanically performed, as to require a greater exertion of the judgment and rational faculties than is sufficient to accomplish many matters of greater importance. The inventor came over to Britain in 1785, where he remained above a year with his automaton.

It was a figure as large as life, in a Turkish dress, sitting behind a table, with doors of three feet and a half in length, two in depth, and two and a half in height. The chair on which it sat was fixed to the table, which ran on four wheels. The automaton leant its right arm on the table, and in its left hand held a pipe: with this hand it played after the pipe was removed. A chess-board of 18 inches was fixed before it. This table, or rather cup-board, contained wheels, levers, cylinders, and other pieces of mechanism, all which were publicly displayed. The vestments of the automaton were then lifted over its head, and the body was seen full of similar wheels and levers. There was a little door in its thigh, which was likewise opened; and with this, and the table also open, and the automaton uncovered, the whole was wheeled about the room. The doors were then shut, and the automaton was ready to play; and it always took the first move.

At every motion the wheels were heard; the image moved its head, and looked over every part of the chess-board. When it checked the queen it shook its head twice, and thrice in giving check to the king. It likewise shook its head when a false move was made, replaced the piece, and made its own move; by which means the adversary lost one.

M. de Kempelen remarked that the most surprising circumstance attending his automaton was, that it had been exhibited at Presburg, Vienna, Paris, and London, to thousands, many of whom were mathematicians and chess-players, and yet the secret by which he governed the motion of its arm was never discovered. He prided himself solely in the construction of the mechanical powers, by which the arm could perform ten or twelve moves. It then required to be wound up like a watch, after which it was capable of continuing the same number of motions.

The automaton could not play unless M. de Kempelen or his substitute were near it to direct its moves. A small square box, during the game, was frequently consulted by the exhibitor; and herein consisted the secret, which he said he could in a moment communicate. He who could beat M. de Kempelen was, of course, certain of conquering the automaton. It was made in 1669. His own account of it was, "C'est une bagatelle qui n'est pas sans mérite du côté du méchanisme: mais les effets n'en paroissent si merveilleux que par la hardiesse de l'idée, et par l'heureux choix des moyens employés pour faire illusion."[1] See AUTOMATON.

ANDROLEPSIA, ἀνδροληψία, in *Grecian Antiquity*, a legal procedure allowed by the Athenians against a community harbouring or protecting persons guilty of murder. Certain officers were empowered to seize three men in the city or house concealing the malefactor till he should be surrendered, or satisfaction be made in some way or other for the murder.

ANDROMACHE, the wife of Hector, the mother of Astyanax, and daughter of Eetion king of Thebes in Cilicia. She is one of the noblest female characters in the *Iliad.* After the death of Hector and the destruction of Troy she became the property of Pyrrhus, and afterwards married Helenus the son of Priam, with whom she reigned over part of Epirus.

ANDROMEDA, in *Astronomy*, a northern constellation behind Pegasus, Cassiopeia, and Perseus. It is supposed to represent a female, and has been named in memory of Andromeda, daughter of Cepheus and Cassiopeia, and wife of Perseus, by whom she had been delivered from a sea-monster, to which she had been exposed to be devoured for her mother's pride in boasting that the beauty of Andromeda surpassed that of the Nereids—(Ovid. *Met.* v.) Minerva translated her into the heavens.

Linnæus gave the name of *Andromeda* to a genus of northern Heaths.

[1] When the automaton chess-player was last exhibited in Britain, in the present century, it was obvious to the writer of this note, that a man was concealed in the apparatus. The ostentatious display of all the wheels and levers was never made simultaneously, but one door of the compartments containing them was shut before another was opened; and thus a sufficient space was always allowed for the concealment of a small person; who, after the apparatus was finally closed, could assume a more convenient position in the figure of the Turk, see through its glass eyes, and direct its arms to make the different moves. The writer knows that a diminutive person always accompanied the exhibitor, who was *en secret* always during the performance, was an excellent chess-player, and when the exhibition was over, appeared from his perspiration and exhaustion as if he had been breathing a confined atmosphere.—ED.

ANDRONICUS I. Comnenus, emperor of the East, was the son of Isaac, and grandson of Alexius Comnenus. Naturally active, martial, eloquent, and licentious, both his virtues and vices soon recommended him to the favour of his cousin Manuel, the reigning emperor; and he was appointed to an important command in Cilicia. Afterwards engaging in a treasonable correspondence with the emperor of Germany and the king of Hungary, he was arrested and thrown into prison. After a confinement of about twelve years, and repeated attempts at escape, he at last effected his purpose, and fled for refuge to the court of the great duke of Russia. The cunning of Andronicus soon found means to regain the favour of the emperor; for, having exerted all his influence, he succeeded in persuading the Russian prince to engage to join his troops with those of Manuel, in the invasion of Hungary. After having obtained a free pardon from the emperor, he again fell under his displeasure by refusing to take an oath of allegiance to the prince of Hungary, his intended son-in-law, presumptive heir to the crown, and was dismissed to his former command in Cilicia. Here his insinuating address captivated the heart of Philippa, daughter of the Latin prince of Antioch, and sister to the empress Maria; and in her company he spent his time in all the amusements that country could afford, till the emperor's resentment put a stop to their correspondence. He now collected a band of adventurers, and undertook a pilgrimage to the Holy Land, where he so far succeeded in gaining the favour of the king and clergy, as to be invested with the lordship of Berytus, on the coast of Phœnicia. In this neighbourhood lived Theodora, the beautiful widow of Baldwin, king of Jerusalem. The personal accomplishments and address of Andronicus captivated her heart, and she became the next victim of his artful seduction, and lived publicly as his concubine. Still pursued by the emperor with unabating resentment, he was forced to take refuge in Damascus, and elsewhere, till at length he settled in Asia Minor. While residing there he made frequent incursions into the province of Trebizond, and seldom returned without success. At length Theodora was made captive by the governor of Trebizond, along with her two children, and sent to Constantinople. Andronicus implored and obtained pardon, but was banished to Œnoe, a town on the Euxine coast.

In the year 1180 Manuel died, and was succeeded by his son Alexius II., a youth about twelve or fourteen years of age, without wisdom or experience. The ambition of Andronicus was now again called into action. A civil war, occasioned by the misconduct of the empress in Constantinople, directed the public mind towards Andronicus, as the only person whose rank and accomplishments could restore the public tranquillity. Incited by the patriarchs and patricians, he marched towards Constantinople, which he entered, took possession of the palace, assumed the office of protector, and consigned the empress, her minister, and many persons of distinction, to death. By the voice of his adherents, he was soon after proclaimed emperor and colleague of Alexius. This conjunction of the royal power was soon dissolved by the murder of the unfortunate Alexius. The dead body being brought into the presence of Andronicus, striking it with his foot, he said, "Thy father was a knave, thy mother a harlot, and thyself a fool." Having arrived at the dignity of sole emperor, A.D. 1183, he continued to sway the sceptre with a mixture of justice and bounty towards his subjects at large; but those whom he feared or hated were treated with the most cruel tyranny. The noble families that were either cut off or exiled by him were all allied to the Comneni. Some of these engaged in revolt; and the public calamity was heightened by an invasion of the Sicilians, in which they took and sacked Thessalonica. A rival without merit, and a people without arms, at last overturned his throne. A descendant from the first Alexius in the female line, named Isaac Angelus, being singled out by Andronicus as a victim to his cruelty, fled to the church of Sophia, and there took refuge with several of his friends. Isaac was instantly raised by the populace from a sanctuary to a throne. On the arrival of Andronicus, who was at this time absent from Constantinople, he found himself deserted by all, and was seized and dragged in chains before the new emperor. All his eloquence was of no avail. Isaac delivered him into the hands of those whom he had injured, and for the space of three days he had to endure all the insults and torments that could be inflicted by a populace exasperated by his crimes. At last two Italians, plunging their swords into his body, put a period to his life. His death, in the 73d year of his age, terminated the dynasty of the Comneni, A.D. 1185.

Andronicus II., *Palæologus*, emperor of Constantinople, was assisted in 1303 by a body of adventurers from the west of Europe, against the Ottomans, who were defeated; but the Greek Emperor found his allies not less destructive than his Asiatic enemies. By using bribes, threats, and force, he got rid of his troublesome friends. He was not, however, permitted to live in peace. His grandson Andronicus rebelled in 1320; and after a succession of contests, the elder competitor was forced to abdicate in 1328. During those disgraceful struggles, the common enemy, the Ottomans, completed the conquest of Bithynia, and advanced within sight of Constantinople. The younger Andronicus lived till 1341.

Andronicus of Cyrrha, a Greek astronomer, about B.C. 100, built at Athens an octagon tower, with figures carved on each side, representing the eight principal winds. A brazen Triton at the summit, with a rod in his hand, turned round by the wind, pointed to the quarter from whence it blew. From this model is derived the custom of placing weathercocks on steeples. A considerable portion of this tower still exists, and, instead of "tower of the winds," it should be called *horologium*, the name by which it is designated by Varro.

Andronicus of Rhodes, a peripatetic philosopher, to whom has been attributed the arrangement of the works of Aristotle, after the manuscripts had been brought to Rome by Sulla. Tyrannion the grammarian placed them in his hands, and certain commentaries on the works of Aristotle have been ascribed to him. Andronicus lived about B.C. 60.

ANDROPHAGI, in *Ancient Geography*, the name of a nation whose country, according to Herodotus, was adjacent to Scythia. Their name, compounded of two Greek words, signifies *man-eaters*. See Anthropophagi.

ANDROS, now Andro, one of the ancient Cyclades, lying between Tenos and Eubœa, one mile distant from the former, and ten from the latter. It had formerly a city of great note, bearing the same name, and situated very advantageously on the brow of a hill which commanded the whole coast. In this city, according to Strabo and Pliny, stood a famous temple dedicated to Bacchus. Near this temple Mutianus, as quoted by Pliny, tells us there was a spring called the *gift of Jupiter*, the water of which had the taste of wine in the month of January, during the feast of Bacchus, which lasted seven days. The Andrians were the first of all the islanders who joined the Persians when Xerxes invaded Greece; and therefore Themistocles, after the victory at Salamis, resolved to attack the city of Andros, and oblige the inhabitants to pay large contributions for the maintenance of his fleet. Having landed his men on the island, he sent heralds to the magistrates, acquainting them that the Athenians were coming against them with two powerful divinities, Persuasion and Force, and they must therefore part with their money by fair means or foul. The Andrians replied that they likewise had two mighty

deities, who were very fond of their island, viz., Poverty and Impossibility, and therefore could give no money. Themistocles, not satisfied with this answer, laid siege to the town, but was unable to take it. It afterwards, however, became subject to the Athenians; and, as we are informed by Plutarch, Pericles, a few years after, sent thither a colony of 250 Athenians. It was soon retaken by the Persians; and, on the overthrow of their empire by Alexander the Great, submitted to him, along with the other islands. On his death it sided with Antigonus, who was driven out by Ptolemy. The successors of the last-mentioned prince held it till the time of the Romans, when Attalus, king of Pergamus, besieged Andros at the head of a Roman army, and, having taken it, was by them put in possession of the whole island. Upon the death of Attalus the republic claimed this island, as well as his other dominions, in virtue of his last will.

Andro contains a town of the same name with 5000 inhabitants, and a great many villages. It is the most fruitful island in the Archipelago, and yields a great quantity of silk. The population has been estimated at about 15,000. When visited by Tournefort, Andro contained seven monasteries, a great number of churches, and a cathedral for the bishops of the Roman Catholic persuasion; but most of the inhabitants were of the Greek communion. It now forms part of the kingdom of Greece. It is about 21 miles long and 8 broad. Long. 24. 50. E. Lat. 37. 50. N.

ANDRYCHOW, a city in the circle of Myslenicze, in the Austrian province of Galizia, on the river Wieprzowka, with a castle, and 3000 inhabitants. It has several manufactories of fine damask and other table-linen.

ANDUJAR, a city of Spain, in the province of Jaen, in Andalucia. It is situated near the mouth of the Jandula, on the south side of the Sierra Morena, which defends it from the cold winds of the north. There is an old bridge over the Guadalquiver at this place. The surrounding country is well watered, and yields abundant harvests of wheat, barley, oil, and wine; and numerous hives of bees furnish abundant supplies of honey and wax. From a whitish clay found here, they manufacture a kind of jars called *alcarrasas*, which are highly esteemed for their property of keeping water cool in the hottest summer weather. It contains a castle, five churches, several monasteries, a theatre, and 10,000 inhabitants. Long. 4. 1. W. Lat. 38. 1. 32. N.

ANDUZE, a town of France, in the department of the Gard, seated on the river Gardon. It carries on a considerable trade in serges and woollen cloth, hats, silk, and leather. Long. 3. 42. E. Lat. 43. 39. N. Pop. 4412.

ANECDOTES (ἀνέκδοτα), a term used by some authors for the titles of *Secret Histories;* but it more properly denotes a relation of detached and interesting particulars. The Greek word signifies *things not yet published,* compounded of α privative and ἐκδίδωμι. Procopius gives this title to a book which he published against Justinian and his wife Theodora. Anecdotes is also an appellation given to such works of the ancients as have not yet been published; in which sense Muratori gives the name *Anecdota Græca* to several writings of the Greek fathers, found in the libraries, and first published by him. Martene and Durand have given a *Thesaurus novus Anecdotorum,* in 5 vols. folio.

ANEL, Dominique, an eminent French surgeon, born at Toulouse in 1679. He is celebrated for his successful treatment of aneurism and *fistula lachrymalis;* and was the inventor of the probe and syringe still known by his name. He appears to have died about the year 1722. His works have been published in Amsterdam 1707, and Turin 1713.

ANEMONE (ἀνεμώνη), a genus of plants belonging to the natural order of Ranunculaceæ. The name was given from the supposition that these plants opened to the blowing of the wind (ἄνεμος). See Botany, and Horticulture.

ANEMOMETER, and Anemoscope, machines for measuring the force, and indicating the course, of the wind. See Physical Geography.

ANEMUR, or Anamour, the most southern point of Asia Minor, on the south coast of Caramania. The castle of Anemur stands six miles east of the cape, on the edge of the sea, and extends about 800 feet by 300. Its citadel is placed on a small rocky eminence, and is in a ruinous state. Long. 32. 50. E. Lat. 36. 1. N.

ANEROID BAROMETER. See Barometer.

ANET, a handsome town of France, nine miles north-east of Dreux. It has the ruins of a castle, built for Diana of Poictiers by Henri II., and destroyed in the revolution of 1792. Pop. 1421. Near it is the plain of Ivry, where Henri IV. defeated the armies of the League under Mayenne, in 1590.

ANEURISM, a term in surgery for a dilated artery.

ANGAR, Angan, or Hindsham, a barren and uninhabited island on the Arabian shore of the Persian Gulf, on the south side of the island of Kishma, about 12 miles in circuit. It must have been formerly inhabited, as it contains the ruins of a considerable town, and many reservoirs of water. It has also two wells, and a stream of good water, which unfortunately become dry in the hot weather. It is covered with pits of salt and metallic ores, and a soft rocky substance resembling lava. The hills, which are overspread with shells of oysters and other fish, abound in wild goats, rabbits, and partridges.

ANGARA, Upper and Lower, two rivers of Asiatic Russia, in the government of Irkutsk. The former rises in the mountains of Nertchinsk, and after a westerly course of about 300 miles, falls into Lake Baikal. The latter has its rise in Lake Baikal, near its southern extremity, and passing the town of Irkutsk, falls into the Jenisei after a course of above 1100 miles, forming several waterfalls in its progress.

ANGARI, or Angarii, in *Antiquity,* public couriers appointed for the carrying of messages. The ancient Persians had their ἀγγαρεῖον, which was a set of couriers on horseback, posted at certain stages or distances, always in readiness to receive the royal dispatches from one, and forward them to another, with wonderful celerity, answering to what the moderns call *posts* (*positi*), as being posted at certain places or stages. The angari were also called by the Persians *astandæ.* This system of couriers was adopted by the Roman emperors, and the supplying of the horses and their maintenance was a burden from which the emperor alone could grant exemption.

ANGARIA. See Angari.

ANGAZYA, one of the Comoro Islands, which lie between the north end of Madagascar and the coast of Zanguebar in Africa, from Lat. 11. to 13. S. It is inhabited by Moors, who trade with several parts of the continent, in cattle, fruits, and various commodities of the island, which they exchange for calicoes and other cotton cloths.

ANGEIOTOMY, in *Surgery,* implies the opening of a vein or artery, as in bleeding; and consequently includes both arteriotomy and phlebotomy.

ANGEL, a spiritual being, the first in rank and dignity among created intelligences. The word *angel* in Greek, (ἄγγελος), signifies a *messenger:* the Hebrew מלאך signifies the same thing. The angels are called in Daniel, ch. iv. ver. 13, &c., עירים, or *watchers,* from their vigilance: for the same reason, in the remains we have of the prophecy attributed to Enoch, they are named *Egregori;* which word imports the same in Greek.

The term *Angel* therefore, in the proper signification of

the word, does not import the nature of any being, but only an office; in which sense angels are called the *ministers of God*, and *ministering spirits*. That there are such beings, invisible and imperceptible to our senses, endued with understanding and power superior to those of human nature, created by God, and subject to him,—ministering to his divine providence in the government of the world,—are truths fully attested by Scripture.

The Romans thought the tutelar genii of those who attained the empire to be of an eminent order, on which account they had great honours shown them. Nations and cities also had their several genii. The ancient Persians so firmly believed in the ministry of angels, and their superintendence over human affairs, that they gave their names to their months, and the days of their months, and assigned them distinct offices and provinces: and it is from them the Jews confess to have received the names of the months and angels, which they brought with them when they returned from the Babylonish captivity; after which, we find they also assigned charges to the angels, and in particular the patronage of empires and nations; Michael being the prince of the Jews, as Raphael is supposed to have been that of the Persians.

Although the angels were originally created perfect, yet some of them sinned and kept not their first estate, but left their habitation, and so, from the most blessed and glorious, became the most vile and miserable of all God's creatures. They were expelled the regions of light, and cast down to hell, to be reserved in everlasting chains under darkness until the day of judgment.

ANGEL, a gold coin first used in France, and introduced into England in the reign of Edward IV. It varied in value from that period till the time of Charles I., from 6s. 8d. to 10s. It was impressed with St Michael and the dragon; whence the name.

ANGELICA, a genus of plants of the natural order of the Umbelliferæ. See HORTICULTURE.

ANGELICI, in *Ecclesiastical History*, an ancient sect of heretics, supposed to have received this appellation from their excessive veneration of angels; or from their maintaining that the world was created by angels.

ANGELICS, the name of an order of knights, instituted in 1191, by Angelus Flavius Comnenus, emperor of Constantinople: also, of a congregation of nuns, founded at Milan in 1534, by Lousia Torelli countess of Guastalla, who observe the rule of St Augustine.

ANGELO, MICHAEL. See MICHAEL ANGELO BUONAROTTI.

ANGELO, *St*, the name of several towns and castles in Italy, and particularly the castle of St Angelo at Rome.

ANGELUS SILESIUS, a German philosophical poet, was born in 1624 at Glatz, and died at Breslau in 1677. His real name was *Johann Scheffler*, but he is generally known under the assumed name which marks the country of his birth. Brought up a Protestant, and at first physician to the Duke of Würtemburg, he afterwards embraced the Roman Catholic faith and took orders as a priest.

His peculiar religious faith, founded on his early study of the works of Tauler and Böhme, as expressed in his hymns (*Cherubinisches Wanderbuch*), is a mystical pantheism founded on sentiment. The essence of God he held to be love: God, he said, can love nothing inferior to himself: but he cannot be an object of love to himself without going out, so to speak, of himself, without manifesting his infinity in a finite form; in other words, by becoming man. God and man are therefore essentially one. The following are some specimens of his sayings:—"Nothing exists but thou (God) and I; and when we both exist not, God is no more God, and the heavens fall in." "God was not slain for the first time on the cross, for behold he lies there in Abel already slain." "I am nothing without God, and God were nothing without me." The following lines contain sentiments less startling and paradoxical.

* * * *

The wise man never lacks an aim, an end he can fulfil,
He ever has a guiding star, to wit, God's holy will.

* * * *

The rose needs not a *Why*—it blooms because it can,
Considers not itself, and asks no praise from man.

A selection of his hymns, which are very popular in Germany, was published in 1820, by Varnhagen Von Ense.

ANGER, a painful feeling of the mind, excited by receiving an injury or affront, and accompanied with a disposition to retaliate on the author of the injury. Bishop Butler observes that anger is far from being a selfish passion, since it is produced by injuries offered to others as well as to ourselves, and was designed by the Author of nature not only to excite us to act vigorously in defending ourselves from evil, but to interest us in the defence or rescue of the injured and helpless, and to raise us above the fear of the proud and mighty oppressor.

The same author makes an important distinction, as Dr Reid observes (*Active Powers*, Essay 3), "between sudden anger or resentment, which is a blind impulse arising from our constitution, and that which is deliberate. The first may be raised by hurt of any kind; but the last can only be raised by injury, real or conceived. Both these kinds of anger or resentment are raised whether the hurt or injury be done to ourselves or to those we are interested in."

Physicians and naturalists have recorded instances of extraordinary cases produced by anger. Borrichius cured a woman of an inveterate tertian ague, which had baffled the art of physic, by putting the patient into a furious fit of passion. Valeriola made use of the same means with success in a quartan ague. The same passion has been equally salutary to paralytic, gouty, and even dumb persons; to which last it has sometimes given the use of speech. Etmüller gives instances of very singular cures wrought by anger: among others, he mentions a person laid up by the gout, who being provoked by his physician, flew upon him, and was cured. It has often, on the other hand, been productive of fatal effects. We meet with several instances of princes to whom it has proved mortal, *e.g.* Valentinian the First, Wenceslaus, Matthias Corvinus king of Hungary, and others. There are many instances where it has produced epilepsy, jaundice, cholera, diarrhœa, &c.

ANGERBURG, a circle in the government of Gumbinnen, and province of East Prussia, formerly a part of Poland. It extends over 374 square miles, or 239,360 acres. It is watered by the Angerap, which rises in several lakes, with which the district abounds. Population in 1849, 31,310, engaged in raising corn and flax, and in fresh-water fishing. The females are all employed in spinning linen yarn. Its capital bears the same name, and contained 240 houses and 3451 inhabitants.

ANGERMANNLAND, an old province of Sweden, now forming a part of the province of West Nordland.

ANGERMUNDE, a circle in the government of Potsdam, and province of Brandenburg, in Prussia. It extends over 503 square miles, or 321,920 acres; comprehends six cities, two market-towns, 64 villages; and in 1849 contained 5006 dwellings, and 55,640 inhabitants. The river Oder washes its eastern boundary, and receives the several smaller streams by which it is watered. The borders of the rivers present some excellent meadow-land, on which many cattle are pastured. It produces good corn, tobacco, flax, and abundance of garden fruit. There is much wood land, and several lakes which yield fish in great plenty. The capital,

of the same name, has three churches; and in 1849 contained 373 houses, and 4501 inhabitants, whose chief occupation is making snuff and tobacco.

ANGERONA, or ANGERONIA, in *Mythology*, the name of a mysterious deity whom the Romans prayed to for the cure of the *quinsy*, in Latin *angina*. Pliny calls her the *goddess of silence* and *calmness of mind*, who banishes all uneasiness and melancholy. She is represented with her mouth covered, to denote silent patience. Her statue was erected in the temple of the goddess Volupia, to show that a patient enduring of affliction leads to pleasure.

ANGERS, the ancient *Juliomagus*, a fortified city of France, capital of the arrondissement of the same name, and of the department of Maine and Loire. It is situated on the Mayenne, five miles from its junction with the Loire, and 48 miles E.N.E. of Nantes. It is the seat of a bishop, and of a royal court of justice. Among its buildings may be noticed a fine old cathedral in which Margaret of Anjou was buried, an ancient castle once the residence of the Dukes of Anjou, and the court-house. It has also three parish churches, an academy, a school of arts and trades, a library with 35,000 volumes, a picture gallery, a botanic garden, a museum of natural history, a theatre, &c. The upper and lower town are separated by the River Mayenne. Though lately much improved, it is an ill-built city, and has an air of meanness. It has sailcloth and cotton factories; sugar and wax refineries; tanneries; and a considerable trade in wine, corn, and slates. In its neighbourhood are extensive slate quarries, which give employment to about 3000 workmen. Pop. in 1846, 40,628. Lat. 47. 28. N. Long. 0. 33. W. The arrondissement of the same name is divided into 9 cantons and 88 communes, and by the census of 1846 the population amounted to 152,406.

ANGERSTEIN, JOHN JULIUS, a distinguished patron of the fine arts, was a native of St Petersburg, but of German extraction, and settled in London about the year 1749, where he became one of the most eminent merchants of that period. On Mr Angerstein's death in 1822, his celebrated collection of pictures, consisting of about forty of the most exquisite specimens of the art, was purchased for the use of the public by the English Government, for the sum of L.60,000. This collection was exhibited for some time at the house of the late proprietor in Pall Mall; and became the nucleus of the magnificent collection in the National Gallery, where it was exhibited on the opening of that institution in 1837.

ANGILBERT, ST, secretary and prime minister of Charlemagne, was the most distinguished poet of his age. After filling the highest offices under that monarch with ability and distinction, and receiving the hand of his daughter Bertha in marriage, he retired in 790 to the monastery of Saint Riquier, of which in 794 he was made abbot. He left this retreat from time to time when the king required his services, and in 800 assisted at Rome at his coronation. He died in 814.

Angilbert was called by Charlemagne the *Homer* of his time, but with what justice we cannot say. A poem of his in 68 elegiac verses, addressed to Pepin king of Italy on his victory over the Huns, exists in the collection of Duchesne; another in 30 verses devoted to the praises of St Eloi and St Riquier is to be found with the poems of Alcuin, of whom Angilbert was a pupil and correspondent.

ANGINA PECTORIS, among *Physicians*, is used to signify an anomalous or spasmodic affection of the chest, commonly connected with a diseased state of the heart or large bloodvessels.

ANGITIA, or ANGUITIA (from *Anguis*) an Italian divinity, was believed to have once been a mortal woman, and to have taught the people the use of antidotes for the poison of serpents. After death she received divine honours from the Marsians and Marrubians about the shores of lake Fucinus. She has also been identified with Medea.—Virg. *Æneid*. vii. 759; Serv. *ad Æn*. vii. 750; Sil. Ital. viii. 500.

ANGHIERA, or ANGERA, a beautiful town of Austrian Lombardy, 38 miles north-west of Milan. It stands on a height on the eastern side of the Lago Maggiore.

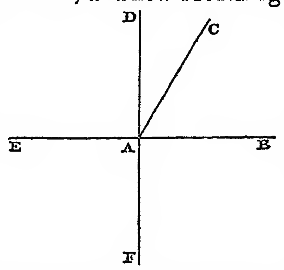
ANGLE. This term is, owing to the poverty of language, employed to signify very different things. In Plane Geometry, it means the opening or separation of two straight lines which meet in a point; but in Solid Geometry, it variously denotes the deviation of a straight line from a plane, the divergence of one plane from another at their line of junction, or even a cluster of plane angles terminating in a common summit. This diversified application of the same word is not likely, however, among mathematicians, to occasion any misconception. But it would be more perspicuous, and certainly more philosophical, to imitate the practice of naturalists in framing a set of cognate words to express the several transitions of meaning.

The word *angle* was drawn from common discourse into the vocabulary of science. Its primitive sense, in all the languages in which it can be traced, is merely a *nook* or *corner*; but it has acquired a more precise and extensive application in its transfer to geometry. In its simplest form, it now denotes generally the *divergence* or difference of direction between two concurring straight lines. Yet a learner still experiences some difficulty in seizing the correct idea of its nature, which has always baffled the attempts of authors to reduce to the terms of a strict definition. Apollonius, at once the most elegant and inventive of the Greek geometers, was satisfied with representing an angle as a *collection of space about a point*,—a description which is not only extremely loose, but which intimates quite a different conception. Euclid, the great compiler of the *Elements*, has defined an angle to be the *κλισις*, or *mutual inclination of two straight lines that meet*. But, in strict language, this definition should apply only to the acute angle, in which one of the sides leans towards the other, and deflects from the perpendicular. Without an extension of the meaning of the term *inclination*, it will not include the obtuse angle, and far less comprehend angles in general; which, since they are capable of repeated additions, must evidently, as much as lines themselves, be susceptible of all degrees of magnitude.

It is indeed impossible, by any combination of words, to express completely and accurately the primary notions which form the ground of geometrical science. The more profitable task is to trace the process by which the mind, refining on external observation, comes to acquire such abstract ideas. We seem to get the idea of *length*, or of *linear extension*, by viewing *progressive* motion; and the enlarged conception of *angles*, or of *angular magnitude*, is easily attained, from the contemplation of *revolving* motion. In opening, for instance, the legs of a pair of compasses, we perceive that their difference in direction gradually increases, keeping pace with the turning at the joint. The quantity of this opening properly constitutes the measure of an angle; and an entire revolution, which brings the moving side of the angle back to its first position, furnishes a *standard* of reference. The bisected revolution marks the divergence of a directly opposite position, or that of two segments of a straight line at their point of separation; and the half of this, again, or the divergence of a line proceeding from the same point, and turned equally aside from both segments, is the *right angle*, which, therefore, being constant, serves to measure all the rest.

Suppose an inflexible straight line AB to turn from right

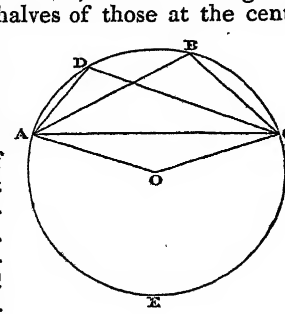
to left, about the point or vertex A. It first comes to the position AC, then to AD, next to AE, and now returning it reaches AF, and lastly it gains its original site AB. The angles thus formed at the point A arise from the combination of successive openings. The angle BAD is composed of BAC and CAD; the angle BAE, or that of direct opposition, is compounded of BAC, CAD, and DAE; and the entire circuit is made of the accumulated angle BAC, CAD, DAE, EAF, and FAB. This circuit, being quartered by the straight lines BE and DF, is divided at the vertex A into four right angles. By comparison, therefore, the angle BAC is acute, and CAE obtuse.



But the side AB can attain the direction AC either by moving onwards, or by turning backwards through the points F, E, and D. The angle compounded of the openings BAF, FAE, EAD, and DAC, may hence be termed appropriately the *reverse* of BAC. The defect of an angle from a right angle is called its *complement*, the defect from two right angles its *supplement*, and the defect from four right angles, or the entire circuit, might be conveniently named its *explement*. Thus, CAD is the *complement* of the angle BAC, CAE is its *supplement*, and the reverse angle BAC its *explement*.

If we consider attentively the formation of angles about a point, we shall be convinced that two concurring straight lines do not contain merely a single angle, but involve an indefinite multitude of angles; in short, that they comprehend all the revolutions and parts of a revolution by which the one line would successively attain the direction of the other. Hence AB will, after describing repeated revolutions, always return into the same position AC. Thus, if A represent the measure of an angle, and C that of a whole circuit, or four right angles; then the primary angle will include likewise $A+C$, $A+2C$, $A+3C$, $A+4C$, continued for ever. Of those successive angles, A, $A+C$, $A+2C$, $A+3C$, $A+4C$, &c. the sines, tangents, and secants are severally the same; and so are the versed sines, the cosines, cotangents, and cosecants. This extension of the doctrine of angles is of the greatest importance in the higher branches of geometry, in the application of trigonometrical formulæ, and in algebraical analysis.

Euclid, in the course of his reasoning, has frequent occasion to combine angles together; and yet he never ventures beyond the consideration of those angles which are less than two right angles. Had he composed his *Elements* after the science of trigonometry came to be cultivated, he could not have failed to take more enlarged views of angular magnitude. In consequence of his narrow conception of the constitution of angles, the Greek geometer is not a little cramped sometimes, and obliged to adopt a circuitous mode of demonstration. For instance, in the 20th prop. of his third book, that "the angles at the circumference are the halves of those at the centre standing on the same arc," he quite overlooks the case of obtuse angles at the circumference. But, in the annexed figure, the angle ABC is clearly the half of the *reverse* angle AOC at the centre, which is subtended by the large arc AEC. It hence follows that the obtuse angles ABC and ADC contained in the same segment must be equal, since they are both of them halves of the same *reverse* angle AOC. Yet, in demonstrating this very obvious corollary, Euclid is constrained to divide the obtuse angles into portions which are shown to be the halves of corresponding angles at the centre. For the same reason he finds it necessary to give a distinct demonstration of the celebrated proposition, that "the angle contained in a semicircle is a right angle." But this property ought likewise to be considered as a mere corollary; for if the radii OA and OC were supposed to extend in one straight line, and thus form the diameter of the circle, their angle AOC would become equal to two right angles, and consequently ABC, its half, would be one right angle. See Leslie's *Geometry*. (J. L.)



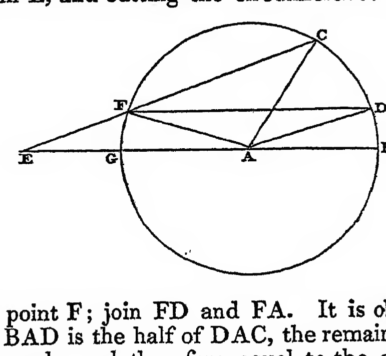
ANGLE *of Incidence*, in *Optics*, the angle which a ray of light makes with a perpendicular to that point of the surface of any medium on which it falls; though it is sometimes understood of the angle which it makes with the surface itself.

ANGLE *of Refraction* now generally means the angle which a ray of light, refracted by any medium, makes with a perpendicular to that point on the surface of which it was incident; but has sometimes been understood of the angle which it makes with the surface of the refracting medium itself.

ANGLE, *Trisection of*. The attempts of the Greek mathematicians to *Double a Cube*, and to *Trisect an Angle*, were their first steps beyond the limits of elementary geometry. They soon perceived that such problems cannot be solved by any combination of mere straight lines or circles. To this conclusion they were led directly by the application of *geometrical analysis*, a beautiful instrument of discovery which Plato had recently invented or improved. Their investigations pointed at some curves of a higher order than the circle, and opened to them a wide and interesting field of research.

The analysis of the trisection of an angle, conducted in two different ways, terminates in the construction of the *conchoid*, a complex curve which was first proposed by Nicomedes. As the subject is very curious, and throws great light on the theory of angular magnitude, we shall here not only give both the ancient methods of investigation, but subjoin a third which is due to the sagacity of Newton.

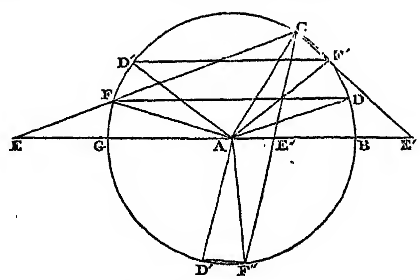
1. Let it be required to trisect the angle BAC or the arc BC. Suppose the thing already done, and the angle BAD to be the third part of the given angle. From the point C draw CE parallel to AD, meeting the extended diameter in E, and cutting the circumference of the circle in the point F; join FD and FA. It is obvious that the angle BAD is the half of DAC, the remaining part of the whole angle, and therefore equal to the angle DFC at the circumference. But AD and EC being parallel, the angle BAD is equal to AEF, which is hence equal to DFC; and consequently FD is parallel to EB. Wherefore the arc BD is equal to GF, and the angle BAD equal to GAF. The angle AEF is thus equal to EAF, and hence the side EF is equal to AF, the radius of the circle.



To solve the problem, therefore, it would be requisite to inflect from C a straight line CFE, such, that the portion FE, intercepted between the circumference and the diameter, or its extension, should be equal to the radius of the circle. The radius AD, drawn parallel to this inflected line CE, would cut off an angle BAD, which is the third part of the given angle BAC.

But elementary geometry will not in general furnish the means of inflecting CE, according to the required conditions. This must be done either tentatively, that is, by repeated trials, or by the application of a curve, so constituted that every straight line drawn from the *pole* C to the *directrix* BG shall have the portion EF, intercepted by the curve, equal to AB. This curve is, from its general shape or resemblance to a *conch* or shell, named the *conchoid:* it consists of two branches, one above the directrix called the *interior conchoid*, and the other below it called the *exterior conchoid*. The conchoid being described, will, by its intersection with the circumference of the circle, give the point F, and consequently the position of the trisecting line AD′. But such a complex curve must cut the circumference in more points than one, and consequently the problem of angular trisection, viewed in its generality, admits of several answers. In fact, there are always *three* distinct positions of the inflected line CE, which will fulfil the conditions of the problem.

It is curious to examine these different positions of the inflected line. Draw AD′ parallel to the *second* position CE′, and join D′F′, AD′, and AF′. Because AF′ is equal to E′F′, the angle E′AF′ is equal to AE′F′; and, consequently, the exterior angle AF′C is the double of either of these. But CAF′ being an isosceles triangle, AF′C is equal to ACF′, which again is equal to the alternate angle CAD′; wherefore CAD′ is the double of the angle AE′F′; and being likewise the double of CF′D′ at the circumference, the angles CF′D′ and AE′F′ are equal, and, consequently, F′D′ and E′A parallel. Now the angle CAD′ being double of E′AF′ or D′AG, and the angle CAD double of DAB, the arc DCD′ is double of the arcs D′G and DB, which serve to complete the semicir-

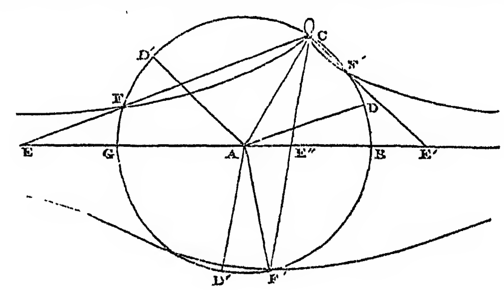


cumference; wherefore this arc DCD′ is two third parts of the semicircumference, or one third of the whole circumference.

In the *third* position AD″ of the trisecting line, draw CF″ parallel to it, and join AF″ and D″F″. The isosceles triangles D″AF″ and AF″E″ have equal vertical angles; and, consequently, the angles at their base are likewise equal; wherefore AF″D″ is equal to the alternate angle F″AE″, and the chord D″F″ parallel to the diameter BG. But the reverse angle CAD″ standing on the arc CD′D″ is double of the angle CF″D″ at the circumference, and therefore double of BE″F″ or of BAD″; and the angle CAD being by the first construction likewise double of BAD, the reverse angle CAD″, together with CAD, must be double of BAD″ and BAD, or the arc CD′GD″ is double of DBD″, which completes the circumference. Hence the arc DD′D″ is two thirds of the circumference.

It thus appears that the construction of the problem assumes three different aspects, and that the trisecting lines, to which a close analogy conducts us, mutually divide the whole circuit into equal portions. These results are perfectly conformable with the theory of angular magnitude. For if A denote the arc BC, and C the whole circumference, this arc will be generally expressed by A, A+C, A+2C, &c.; consequently, the third part will be expressed by $\frac{1}{3}$A, $\frac{1}{3}$A$+\frac{1}{3}$C, $\frac{1}{3}$A$+\frac{2}{3}$C, &c., which evidently correspond to BD, BD′ and BD″. But any farther extension of this progression only brings the trisecting line back into its former positions.

To solve completely, therefore, the problem of the trisection of an angle; from the pole C, on either side of the directrix BG, with a measure equal to the radius of the circle, describe the exterior and the interior or nodated conchoid; draw CF, CF′, and CF″ to the three points of intersection with the circumference, and the radii AD,

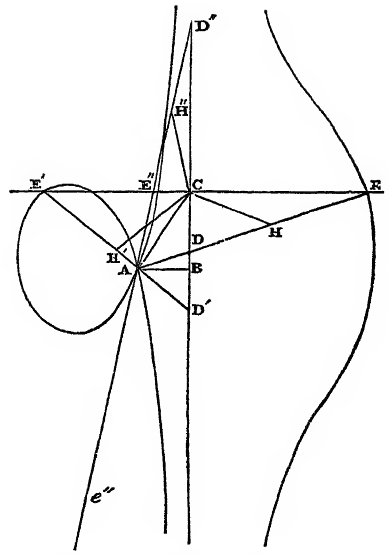


AD′, and AD″ parallel to these will mark the triple section of the angle BAC.

It may be perceived that the exterior branch of the conchoid cuts the under semicircle in another point besides F. This occurs in the extension of the radius CA, or where the diameter passing through C, the extremity of the original arc, meets the opposite circumference; the portion of the inflected line, intercepted below BG by the conchoid, being evidently equal to the radius. The fourth intersection, however, affords no real solution, but only exhibits the amount of repeated division, as completing the arc itself.

2. But another analysis leads to a similar result. Let the angle BAD, as before, be the third part of BAC; draw BC perpendicular to AB, and CE parallel to it, meeting AD produced in E. The right angle DCE would be contained in a semicircle having DE for its diameter; join C with the centre H, and the triangle CHE being isosceles, the exterior angle CHA is double of CEH, or of the alternate angle BAD, and therefore equal to the remaining portion CAD of the divided angle BAC. Whence the triangle ACH is isosceles, and the side CA equal to HC, or the diameter DE must be double of AC.

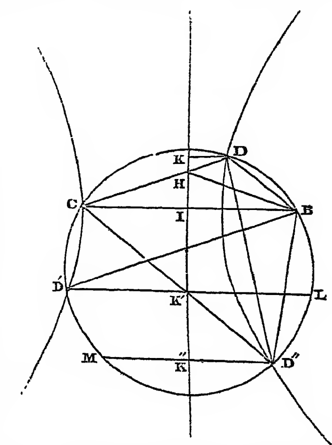
The construction of the problem is thus reduced to the drawing from the vertex of the given angle a straight line ADE, such, that the part DE, intercepted between the perpendiculars BC and CE, shall be equal to the double of AC. This can only be done by describing a conchoid from the pole A to the directrix BC, and with the double of AC as the measure; the intersection of the curve with the perpendicular CE will determine the position of the trisecting line ADE. The exterior branch of the conchoid will cut the perpendicular in the point E, and the interior or nodated branch will meet and cross it at the two points E′ and E″. The radiating lines AE, AE′, and AE″, or its extension Ae″, will indicate the complete trisection of the angle BAC. These lines will be found, as in the first construction, to make angles with each other that are equal to the thirds of an entire circuit. It may be worth while to examine the several cases.



In the *second* position D′AE′ of the trisecting line, draw CH′ to the middle point. Because the triangle E′H′C is isosceles, its exterior angle CH′A is double of CE′H′, or of the angle BAD′; but H′CA being also an isosceles triangle, CH′A is equal to CAH′, and consequently double of BAD. Add CAD, which is double of BAD, and the compound angle DAE′ is double of DAD′, which would complete two right angles; whence DAE′ is two thirds of two right angles, or one third of a whole circuit.

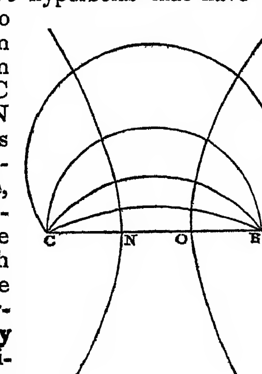
In the *third* position, AE″D″ of the trisecting line, or rather its extension Ae″, draw CH″ to bisect E″D″. The triangles CH″D″ and ACH″ are then isosceles, and consequently the angle CAD″ or CH″A is double of CD″A; but CAE is likewise double of CEA, and therefore the combined angle D″AE is double of the angles CD″A and CEA. Now this angle D″AE, together with the two angles CD″A and CEA, is evidently equal to the exterior angle DC″E or a right angle. Whence D″AE is two thirds of a right angle, or one third of two right angles, and therefore the adjacent angle DAe″ is two thirds of two right angles, or one third of a whole circuit.

3. The simplest and most elegant solution of the trisection of an arc was indicated by Pappus, and is given in Castillon's Commentary on Newton's *Universal Arithmetic.* The problem is there reduced to the combination of the circle with a certain kind of hyperbola. But the general property of the directrix, which belongs to all the conic sections, or the lines of the second order, affords the readiest mode of investigation. Let the arc BD be the third part of BDC. Complete the circle, and draw the chords BD, BC, and CD. The arc CD is evidently double of BD, and therefore the angle CBD is double of BCD. Bisect the angle CBD by the straight line BH, let fall the extended perpendicular, and draw the parallel DK. The triangle CHB is evidently isosceles, and HI bisects the base CB. But the triangle CBD having its vertical angle at B bisected, the side CB is to BD as the segment CH of the base to HD; that is, since the triangles CHI and DHK are similar, as CI to KD; wherefore, CB being the double of CI, BD is likewise double of DK. The ratio of the distances BD and DK is thus given, while the point B is given, and the straight line IH given in position. Whence, from the theory of lines of the Second Order, the locus of the point of section D is an *hyperbola*, of which B is a focus, and IH a directrix, with the determining ratio of two to one. Let this construction be made, and the arc CDB is trisected in D. For since BD is, from the property of the curve, double of DK, it is evident that BC is to CI as BD to DK; and the triangles CIH and KDH being similar, and CI to CH as DK to DH, it follows that BC is to CH as BD to DH, or alternately BC is to BD as CH to DH. Wherefore the vertical angle CBD is bisected by BH, or the angle CBD is double of CBH or of BCD, and consequently the arc CD is double of BD, or BD itself is the third part of the whole arc CDB.



But the opposite branch of the hyperbola, which passes through C, also comes into play; and the intersection of these two branches with the circle assigns three different positions of the point D, separated from each other by intervals equal to the third of the whole circumference. Thus, in the *second* position D′, produce the perpendicular D′K′ to the opposite circumference L; and since BD′ is double of D′K, it must be equal to the chord D′L, and consequently the arc BDCD′ is equal to LD″MD′. Wherefore the double of BDCD′, together with the interval BL or CD′, is equal to the whole circumference; that is, the double of DCD′, with the double of BD and CD′, is equal to the whole circumference; and since the double of BD is DC, the triple of the arc DCD′ must complete the circumference. In the *third* position D″, produce the perpendicular D″K″ as before: the double of this, or the chord MD″, is hence equal to D″B, and the arc BLD″ equal to DM: consequently the double of BLD″, with the compound arc BDCM, completes the circumference; but D″M being parallel to BC, the arc BLD″ is equal to CD′M, and therefore three times the arc BLD″, with the arc BDC, or the triple of BD, will fill up the circumference, or the arc DBD″ is a third part of it.[1]

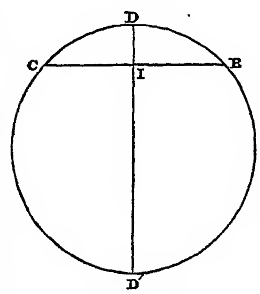
The trisection of innumerable arcs described on the same chord is rendered very conspicuous by combining the separate branches of two hyperbolas that have the determining ratio of two to one, and their foci situate in the extremities of the given line. Thus, let the chord BC be trisected at the points N and O, and from B and C, as distinct foci, and in the determining ratio of two to one, describe branches of independent hyperbolas. All the arcs erected on BC are each of them divided by those curves into three equal portions. These arcs, as they flatten, approach to the trisected chord CNOB on the



[1] For more illustration of this subject, see Leslie's *Geometry of Curve Lines.*

one hand; and as they become enlarged, they constantly tend, on the other, to the complete circumference which the asymptotes of the hyperbola, making angles on each side of the axis equal to two thirds of a right angle, would themselves trisect.

It may be observed in general, that the section of an arc or angle admits of as many different answers as the number of divisions proposed. Thus, the quadrisection would give four distinct results, and a quinsection would involve no fewer than five separate products. Nay, the bisection itself of an arc, though within the limits of the most elementary geometry, yet brings out a double result. Thus, the arc CDB is bisected by the perpendicular or diameter DID′, which not only gives BD for the half of that arc, but also BDCD′, or the same half-arc augmented by a semicircumference.



These conclusions agree with the results derived from the general theory of equations. The expression for the sine of a multiple arc is always an equation of corresponding dimensions, which therefore admits of as many distinct roots as the index contains units.

The ancient geometers were only acquainted with the original division of the circumference into two, three, or five equal portions. The only subdivisions were obtained from the differences of those arcs or their continued bisection. But the very ingenious Professor Gauss has discovered a series of more complex regular polygons, which may be inscribed in a circle by elementary geometry. The expression $2^n + 1$, when a prime number, will represent the sides of the figure: for the general equation of a cosine of the section can be decomposed into quadratics of the simplest kind, which can be constructed by the repeated application of circles and straight lines. A polygon of 17 sides is the first that occurs after the pentagon; and then follow the polygons of 257, 65537, &c. (J. L.)

ANGLES, an ancient German nation, originally a branch of the Suevi; who, after various migrations, settled in that part of Denmark now called Schleswig. (A district in Holstein still bears the name of Angeln.) Here they were known, even in the time of Tacitus, by the name of *Angli*. The origin of this name is variously accounted for. According to Saxo Grammaticus, they were called *Angli*, from one Angulus, son of Humblus king of Denmark. Goropius derives their name from the Saxon word *Angel* or *Engel*, signifying a fish-hook; the Angles, like the other Saxon nations, being greatly addicted to piracy, and on that account being so named by the neighbouring nations; as if, like hooks, they caught all that was in the sea. To this nation the British ambassadors are said to have applied when soliciting succours against the Scots and Picts. The Angles, therefore came over in greater numbers than any other Saxon nation, and accordingly had the honour of giving the name of *Anglia* to England.

ANGLESEA, or ANGLESEY, an island of North Wales, forming the county of that name. It is divided from the main island of Great Britain by the narrow armlet of the sea called the Straits of Menai. Over this water a magnificent suspension bridge was completed in January 1826. Still more recently, in 1850, a railway has been carried across the strait through a stupendous tubular bridge, constructed of iron. See MENAI STRAIT, and TUBULAR BRIDGES. The extent of the county is about 271 square miles, or 173,440 acres. The soil is but moderately fertile; but in average years it yields more barley and oats than the consumption requires. The surplus generally finds a market in Liverpool. A number of horned cattle, sheep, and hogs, are annually sent over the Menai. The most valuable product of the island arises from the mines. The chief of these, the Parys mine, was once the most abundant in copper ore of any mine in the world; and even in the water lodged beneath the bed of ore, quantities of nearly pure copper are obtained by exposing it to iron. A mine of lead, but rich in silver, has been discovered near the same mountain. Quarries of various kinds of marble, and mines of asbestos, also are found on the island. Coal is obtained at Maltreath in considerable quantities. The mines have, however, of late greatly diminished in productiveness, especially those of copper. The herring fishery in some years gives employment to a portion of the inhabitants.

The island has been celebrated in the most remote periods as the seat of the druidical pontiff, and the great nursery of the instructors in that kind of religion or superstition, of which but little has been handed down by any other mode than by tradition, and which is attended with the doubts and uncertainty naturally arising from that mode of communication. See the article DRUID.

At present the Welsh language, of the northern dialect, is almost the exclusive language of the peasantry; but in the towns, especially at Holyhead, English is very generally understood. The county is divided into 6 hundreds and 76 parishes. The number of inhabitants in 1841 was 50,891; and in 1851, 57,327. The county returns one member to parliament, and one is also returned by the boroughs of Beaumaris, Holyhead, Amlwch, and Llangefni.

ANGLING.

ANGLING, or the art of fishing with rod and line, includes those branches of the piscatorial trade which are usually followed, not so much for profit, as for pleasant recreation. That the practice of "casting angles into the brook" had its origin in necessity, the mother of so many inventions, can hardly be doubted; but it is equally clear that the refined skill exhibited in this pursuit at the present day has been derived from leisure and the love of sport, aided by the more delicate gear which modern ingenuity has invented for the deception of the finny race.

The comparative merits of angling, and of the kindred occupations of the fowler and the huntsman, are not likely to be determined by any portraiture which a lover of these exciting amusements might draw of their various excellencies, but must depend on the tone and temper of mind possessed by different persons, and their greater or less accordance with individual tastes. This much, however, may be safely stated as a general and admitted truth, that the value of a pursuit increases in proportion as it becomes attainable by the mass of our fellow-creatures; and as angling is a much cheaper and more convenient pleasure than either hunting or shooting, it may, in so far as regards those advantages, claim a decided preference. Be it remembered that Dr Johnson's description of a rod with a fly at one end and a fool at the other

 is not admitted among the memorabilia of the lovers of old Izaak Walton.

The recreation of angling has been followed by many of the best and wisest of men in modern ages. Sir Henry Wotton found from experience, that after prolonged study or worldly occupation, it was "a rest to his mind, a cheerer of his spirits, a diverter of sadness, a calmer of unquiet thoughts, a moderator of passions, a procurer of contentedness;" and, besides the immediate excitement of the sport itself, few occupations yield so much pleasure to the lovers of rural scenery and the admirers of the picturesque. The most beautiful scenes in nature usually adorn or consist of the banks of lakes and rivers; and the composition of a perfect landscape, whether in nature or art, is incomplete without the accessory of either tranquil or flowing waters. The pursuits of the artist and the angler are therefore peculiarly compatible, and each lends an interest to the other.

The lofty woods, the forests wide and long,
Adorn'd with leaves and branches fresh and green,
In whose cool bowers the birds with many a song
Do welcome with their quire the summer's queen;
The meadows fair, where Flora's gifts among
Are intermixed with verdant grass between;
The silver scaled fish that softly swim
Within the sweet brook's crystal watery stream:

All these, and many more of HIS creation,
That made the heavens, the angler oft doth see;
Taking therein no little delectation,
To think how strange, how wonderful they be;
Framing thereof an inward contemplation,
To set his heart from other fancies free;
And whilst he looks on these with joyful eye,
His mind is rapt above the starry sky.

Markham, in his *Country Contentments*, describes not only the outward apparel, but the inward qualities, of an angler. He must be generally accomplished in all the liberal sciences, and, as a grammarian, ought to be qualified to write and discourse of his art in true and fitting terms. He must be possessed of *sweetness of speech* to entice others to so laudable an exercise, and of strength of argument to defend it against envy and slander. "Then must he be strong and valiant, neither to be amazed with storms, nor affrighted with thunder; and if he is not temperate, but has a gnawing stomach that will not endure much fasting, but must observe hours, it troubleth the mind and body, and loseth that delight which only maketh pastime pleasing." "He must be of a well-settled and constant belief, to enjoy the benefit of his expectation; for then to despair, it were better never to be put in practice: and he must ever think when the waters are pleasant, and any thing likely, that there the Creator of all good things hath stored up much of plenty; and though your satisfaction be not as ready as your wishes, yet you must hope still, that with perseverance you shall reap the fulness of your harvest with contentment. Then he must be full of love both to his pleasure and his neighbour—to his pleasure, which otherwise will be irksome and tedious—and to his neighbour, that he never give offence in any particular, nor be guilty of any general destruction: then he must be exceeding patient, and neither vex nor excruciate himself with losses or mischances, as in losing the prey when it is almost in the hand, or by breaking his tools by ignorance or negligence; but with pleased sufferance amend errors, and think mischances instructions to better carefulness."

In regard to the antiquity of angling, it has been traced by some to the time of Seth, who is asserted to have taught it to his sons; and so highly have others esteemed the knowledge of the art, as to maintain that its rules and maxims were engraven on those pillars by which an acquaintance with music, the mathematics, and other branches of useful knowledge, was preserved by God's appointment from extinction in the days of Noah. It is frequently alluded to in the holy Scriptures; as in Isaiah, xix. 8, "The fishers also shall mourn, and all they that cast angle into the brooks shall lament, and they that spread nets upon the waters shall languish;" so in the prophet Habbakuk, i. 15, "They take up all of them with the angle, they catch them in their net, and gather them in their drag; therefore they rejoice and are glad." We deem it unnecessary to multiply quotations from ancient authors, whether sacred or profane; but shall rest satisfied with pointing out, at the close of this article, the principal works on angling which have appeared in our own language, and in relation to the practice of the art in British streams.

As expert angling never was and never will be successfully taught by rule, but is almost entirely the result of assiduous and long-continued practice, we purpose being very brief in our disquisition on the subject. We shall commence by stating our belief that fly-fishing, by far the most elegant and interesting branch of the art, ought not to be regarded exclusively as an art of imitation. It no doubt depends on deception, which usually proceeds on the principle of one thing being successfully substituted in the likeness of another; but Bacon's distinctive definitions of simulation and dissimulation place the subject in a truer light. As simulation consists in the adoption or affectation of what is not, while dissimulation consists in the careful concealment of what really is—the one being a positive, the other rather a negative act—so the great object of the fly-fisher is to dissimulate in such a manner as to prevent his expected prey from detecting the artificial nature of his lure, without troubling himself by a vain effort to simulate or assume, with his fly, the appearance of any individual or specific form of insect life. There is, in truth, little or no connection between the art of angling and the science of entomology; and therefore the success of the angler, in by far the greater proportion of cases, does not depend on the resemblance which subsists between his artificial fly and the natural insect. This statement is no doubt greatly at variance, as well with the principles as the practice of all who have deemed fishing worthy of consideration, from the days of Isaiah and Theocritus, to those of Carrol and Bainbridge. But we are not the less decidedly of opinion, that in nine instances out of ten a fish seizes upon an artificial fly as upon an insect or moving creature *sui generis*, and not on account of its exact and successful resemblance to any accustomed and familiar object.

It may be asked, upon what principle of imitative art the different varieties of salmon-fly can be supposed to bear the most distant resemblance to any species of dragonfly, to imitate which we are frequently told that they are intended? Certainly no perceptible similarity in form or aspect exists between them, all the species of dragonfly, with the exception of one or two of the sub-genus Calepterix, being characterized by very clear, lace-like, pellucid wings, entirely unadorned by those fantastic and gaudy colours, borrowed from the peacock and other "birds of gayest plume," which are made to distinguish the supposed resemblance. Besides, the finest salmon-fishing is in mild weather during the colder seasons of the year, and in early spring, several months before any dragonfly has become visible on the face of the waters, as it is a summer insect, and rarely makes its appearance in the perfect state till the month of June. If they bear no resemblance to each other in form or colour, how much more unlike must they be, when, instead of being swept down the current, as a real one would be, the artificial fly is seen cross-

ing and recrossing every stream and torrent, with the agility of an otter, and the strength of an alligator? Now, as it is demonstrable that the artificial fly generally used for salmon bears no resemblance, except in size, to any living one; that the only tribe which, from their respective dimensions, it may be supposed to represent, does not exist in the winged state during the period when the imitation is most generally and most successfully practised; and if they did, that their habits and natural powers totally disenable them from being at any time seen under such circumstances as would give a colour to the supposition of the one being ever mistaken for the other; may we not fairly conclude that, in this instance at least, the fish proceed upon other grounds, and are deceived by an appearance of life and motion, rather than by a specific resemblance to any thing which they had previously been in the habit of capturing? What natural insect do the large flies, at which sea-trout rise so readily, resemble? These, as well as gilse and salmon, frequently take the lure far within the bounds of the salt-water mark; and yet naturalists know that no such thing as a salt-water fly exists, or at least has ever been discovered by their researches. Indeed no true insect inhabits the sea. What species are imitated by the palmer, or by three fourths of the dressed flies in common use? An artificial fly can, at the best, be considered only as the representation of a natural one which has been drowned, as it is impossible to imitate the dancing or hovering flight of the real insect over the surface of the stream; and, even with that restricted idea of its resemblance to nature, the likeness must be scarcely perceptible, owing to the difference of motion, and the great variety of directions in which the angler drags his flies, according to the nature and special localities of the current, and the prevailing direction of the wind.

The same observations apply, with almost equally few exceptions, to bait-fishing. The minnow is fastened upon swivels, which cause it to revolve upon its axis with such rapidity, that it loses every vestige of its original appearance; and in angling with the par tail, one of the most killing lures for large trout, the bait consists of the nether half of a small fish, mangled and mis-shapen, and in every point of view divested of its natural form.

Fly-fishing has been compared, though by a somewhat circuitous mode of reasoning, to sculpture. It proceeds upon a few simple principles, and the theory is easily acquired, although it may require long and severe labour to become a great master in the art. Yet it is needless to encompass it with difficulties which have no existence in reality, or to render a subject intricate and confused, which is in itself so plain and unencumbered. In truth, the ideas which at present prevail on the matter degrade it beneath its real dignity and importance. When Plato, speaking of painting, says that it is merely an art of imitation, and that our pleasure arises from the truth and accuracy of the likeness, he is surely wrong; for if it were so, where would be the superiority of the Roman and Bolognese over the Dutch and Flemish schools? So also in regard to fishing: The accomplished angler does not condescend to imitate specifically, and in a servile manner, the detail of things; he attends, or ought to attend, only to the great and invariable ideas which are inherent in universal nature. He throws his fly lightly and with elegance on the surface of the glittering waters, because he knows that an insect with outspread gauzy wings would so fall; but he does not imitate (or if he does so, his practice proceeds upon an erroneous principle), either in the air or on his favourite element, the flight or the motion of a particular species, because he also knows that trouts are much less conversant in entomology than M. Latreille, and that their omnivorous propensities induce them, when inclined for food, to rise with equal eagerness at every minute thing which creepeth upon the earth or swimmeth in the waters. On this fact he generalizes,—and this is the philosophy of fishing.

We are therefore of opinion that all, or a great proportion, of what has been so often and sometimes so well said about the great variety of flies necessary to an angler, —about the necessity of changing his tackle according to each particular month throughout the season,—about one fly being adapted solely to the morning, another to noonday, and a third to the evening,—and about every river having its own particular flies, &c. is, if not erroneous, at least exaggerated and misconceived. That determinate relations exist between flies of a certain colour and particular conditions of a river, is, we doubt not, true; but these are rather connected with angling as an artificial science, and have but little to do with any analogous relations in nature. The great object, by whatever means it is to be accomplished, is to render the fly deceptive; and this, in fact, we believe to be more frequently effected when fishing with flies which differ in colour and general appearance from those which are upon the water. When a particular fly prevails upon a river, an artificial one in imitation of it will never resemble it so closely as to appear the same to those below (*i. e.* the fish): on the contrary, a certain degree of resemblance, without any thing like an exact similitude, will only render the finny tribe the more cautious through suspicion; while a different shape and colour, by exciting no minute or invidious comparisons, would probably have been swallowed without examination. Indeed, it seems sufficiently plain, that where means of comparison are allowed, and where exact imitation is at the same time impossible, it is much better to have recourse to a general idea, than to an awkward and bungling individual representation. How often has it been asserted, with all the gravity of sententious wisdom, that the true mode of proceeding in fly-fishing is to busk your hook by the river-side, after beating the shrubs to see what colour of insect prevails. A very expert angler, who perhaps carried the opposite theory rather too far (although he always filled his pannier), was in the habit of stirring the briars and willows to ascertain what manner of fly was not there, and with that he tempted the fishes.

It is admitted, that during mid-summer, when the weather is calm, the sky clear, and the river low, and when what is called fine fishing is necessary, a close imitation both of the appearance and motions of the natural fly may frequently be tried with advantage; in which case the tackle may be allowed to drop gently down the stream: but it more usually happens, from the style of fishing practised during the vernal and autumnal states of a river, that the hook is not deceptive from its appearing like a winged fly which has fallen from its native element, but from its motion and aspect resembling that of some aquatic insect. When the end of the line first falls on the surface of the water, the fish may be deceived by the idea of a natural fly; and it is on that account that the angler should throw his tackle lightly and with accuracy, and it is on that account also that we would advise the more frequent throwing of the line: but so soon as the practitioner begins to describe his semicircle across the river, the character of the lure is changed, and the trout then seizes the bait, not as a drowning insect, but as a creature inhabiting its own element, which had ventured too far from the protection of the shallow shore or the sedgy bank. That this is the case, a subsidiary argument may also be drawn from the fact, that in most rivers the greater number and the finest fish are generally killed by

the drag-fly, which, during the process of angling, swims an inch or two under water.

Nevertheless, as these opinions of ours may not accord with the practice of other anglers, we shall proceed somewhat more methodically to explain a few of the principles of the art as usually received and followed.

The great secret in fly-fishing, after a person has acquired the art of throwing a long and a light line, is perseverance,—that is, constant and continuous exertion. Fish are whimsical creatures, even when the angler, with all appliances and means to boot, is placed apparently under the most favourable circumstances. Let him, however, commence his operations with flies which, upon general principles, he knows to be good,—for example, a water-mouse body and dark wing, hare-ear and moorfowl wing, red hackle and teal or mallard wing. It may frequently happen that for an hour, or even two hours, he will kill nothing; but then it will as often happen that for another couple of hours he will pull them ashore with a most pleasing celerity.

Awake but one, and, lo, what myriads rise!

Next comes a pause of another hour or more, during which little or nothing is obtained, so that if the intermediate period is frittered away, success is doubtful or impossible. We believe that the appetites and motions of the finny tribes are regulated and directed by certain (to us) almost imperceptible changes in the state of the atmosphere, with which, as they do not proceed from any determinate or ascertained principles of meteorological science, it is not easy for the angler to become acquainted; and therefore the only method to remedy the *désagrément* thus arising, is to fish without ceasing as long as he remains by the " pure element of waters." The art of angling, if worthily followed, and with an observant eye, will probably one day or other be the means of throwing considerable light on the science of electricity, at present one of the most obscure, though at the same time the most important and influential, of all the subjects of physical learning.

The best *natural* flies, either to use fresh, or to serve as models for the artificial kinds, are, *first*, the different sorts of stoneflies (*Phryganea* and *Limnephilus*), which are usually found by the water-side. Their common colours are various shades of brown; they have pretty long feelers or antennæ, which, in a state of repose, are bent over their shoulders and along their sides; their wings are held decumbent, or close to the sides. They fly heavily, and are produced from aquatic larvæ called caddis or case-worms, remarkable for their curious dwelling-places, which are hollow tubes composed of sand, small shells, and pieces of wood, agglutinated together, and made heavier or lighter, according to circumstances, that they may the more easily sink or swim. They are open at either end, and the worm crawls along the stones and gravel, by protruding its legs at the anterior extremity. They disencumber themselves from their aquatic habitations, and assume the winged state in spring and the earlier part of summer. *Secondly*, The different kinds of May flies (*Ephemeræ*), called green drakes, &c. are also produced from larvæ, which, for a long time previous to their appearance as perfect insects, have inhabited the waters. There are many species of this genus, all of which are greedily sought for by trout. They are easily known by their tapering abdomens, veined wings, short antennæ, and the long slender setæ or hairs which terminate their bodies. They chiefly abound from May to mid-summer. *Thirdly*, The small black or ant-fly, is the winged female of the common black ant, and occurs in the nests or hills of that insect during the summer and autumnal months.

There is scarcely any season of the year, excepting the winter months, in which an experienced angler may not successfully ply his trade.[1] In the mid-summer season, when the pools are very clear and shallow, and the streams almost dried up, little can be done without a stirring breeze; so also after a heavy summer flood, immediately ensuing a continuance of dry weather, when the mountain torrents are a sheet of dingy foam, and the crystal depths of the river are converted for a time into an opaque flow of muddy water, the fly-fisher's occupation's gone. But when the turmoil ceases, and the soft south wind begins to disperse or break in upon the dense array of clouds, so as to chequer the streams, and rocks, and " pastoral melancholy" of the green mountains with the enlivening beams of the returning sun, with what pleasure does the angler approach the banks of a favourite and accustomed river! How various and delightful are his sensations! Custom cannot stale their infinite variety:—on the contrary, the longer and more assiduously the pleasure is pursued, the greater the immediate enjoyment, and the more extended the train of agreeable remembrances for after-days. How exciting the first cast into a breeze-ruffled pool, when the unwetted gut still lies in rebellious and unyielding circles on the surface, and yet almost at the same moment the sounding reel gives notice that these circles have been instantaneously stretched into a straight and tightened line! Then comes the long and continuous vibration of rod and reel, indicating the secure hooking of a goodly fish; or that sullen and pulse-like tug, by which a still goodlier one, when hooked in a deep pool, frequently manifests a desire to *dig* its way to the bottom; or that more interrupted music which results from the fantastic leaps of some whimsical individual, which skims and flounders on the top of the water like a juvenile wild-duck.

The ordinary rules for fly-fishing are, to be most assiduous when the streams are somewhat disturbed and increased by rain,—when the day is cloudy, and the waters moved by a gentle breeze, especially from the south. If the river contains long placid pools, then a steady stirring breeze is very desirable, as angling in such situations resembles lake-fishing, where nothing can be achieved upon a glassy surface. If the wind is low and the weather clear, of course the best angling is in the swiftest streams, and in those curling and perturbed eddies which head the smoother depths. In fishing the smoother pools of no great depth, be careful that the shadows of neither rod nor angler come upon the surface; but if a person is skilful in other respects, he need not fear his own shadow in a broad river, but wade boldly down the centre of the stream, fishing its various depths and currents before him and on either side. In clear rivers the flies should be small and rather slender-winged; but when the waters are muddy or increased by rain, a larger lure may be

[1] Although Izaak Walton, that " great master in the art of angling," informs us that no man should in honesty catch a trout till the middle of March, yet the grayling is in best condition during the winter season. " I do assure you," says Charles Cotton, in the second part of the Complete Angler, " which I remember by a very remarkable token, I did once take, upon the sixth day of December, one, and only one, of the biggest graylings, and the best in season, that ever I yet saw or tasted; and do usually take trouts too, and with a fly, not only before the middle of this month, but, almost every year, in February, unless it be a very ill spring indeed; and have sometimes in January, so early as new-year's tide, and in frost and snow, taken grayling in a warm sun-shine day for an hour or two about noon; and to fish for him with a grub it is then the best time of all."

made use of. When the streams are brown with rain, an orange-coloured fly is good; in very clear weather a light-coloured one; and a dark fly is advisable for troubled waters.

Though a great deal no doubt depends on a quick eye and an active and delicate hand, we are no great advocates for what is called *striking* a fish. If a large trout rises in a deep pool, it may be of advantage so to do; and this will be sufficiently accomplished by inclining the rod quickly aside, so as to draw out a few inches of the line; for if the reel is not allowed to run, this operation is apt to snap the gut, or otherwise injure the tackle. But if a trout, whether great or small, rises in a current or rapid stream, the sudden change in its position, immediately after it has seized the fly, is generally quite sufficient to fix the barb, without any exertion on the part of the angler.

A variable state of the atmosphere is bad for angling; but neither is a uniformly dull gloomy day the most favourable. It is scarcely possible to lay down any general rules on this branch of the subject. We have half filled a pannier during an electric hail-storm, when "sky lowered and muttered thunder," and the aspect of the day was such as to deter more experienced though less zealous sportsmen from leaving the shelter of their homes. If the river is not too low, we always prefer what in ordinary language might be called a fine cheerful day, more particularly if there is a fresh breeze. And what we would more particularly press upon the notice of the angler, as soon as he becomes master of the line, is, that he should cast his flies more frequently than is the usual practice, and, generally speaking, fish rapidly. This should be more especially attended to in streams where the trout are numerous and not large.

Before enumerating and describing the different kinds of artificial flies in greatest repute, we shall mention a few of the principal materials used by the fly-fisher. The articles which he employs in common with those who prosecute the other branches of the trade, are of course rods, hair and gut lines, reels and hooks, panniers and landing-nets; but in addition to these he must be provided with a great variety of feathers, such as the slender plumes called hackles, from the necks and backs of common poultry, and the wings of a considerable number of birds, such as woodcocks, snipes, rails, plovers, ducks, grouse, partridges, and others. The furs of quadrupeds are also indispensable; and of these the most useful are hares, squirrels, moles, martens, mice, and water-rats.

The most esteemed hackles are the *duns*. The red, striped down the centre with black, and the red with a blackish root, are likewise useful, and more easily obtained. Since the introduction of Spanish poultry (by which name are designated the black breed with white tops), black hackles are now more common than formerly. The proper time for plucking hackles is about Christmas. The feathers of the ostrich and peacock are of frequent service; and for salmon and sea-trout the gaudy plumes of parrots and other brilliantly attired foreign species, however unlike the generality of our northern insects, ought to be collected by every fly-fisher.

The silks commonly used by the angler are of three kinds:—1*st*, Barbers' silk, used double, for splicing the top-pieces of rods; 2*dly*, a more delicate kind, for fastening on the rings through which the reel-line runs; 3*dly*, fine netting silk for whipping hooks and dressing flies. When we mention a pair of small pliers, fine-pointed scissors, needles, and wax, we have noted the principal materials for the angler's trade.

In regard to rods, their length and formation are so much matters of individual taste, that few general rules can be laid down upon the subject. According to Daniel, the wood should be cut about Christmas, and allowed to season for a twelvemonth. Hazel is very generally used, especially that from the *cob-nut*, which grows to a great length, and is for the most part very straight and taper. The but-end should rather exceed an inch in diameter, and the shoots for stocks, middle pieces, and tops, should be as free from knots as possible. The tops are made from the best rush ground shoots. All these pieces should be kept free from moisture till the ensuing autumn, when such as are required to form a rod are selected; and, after being warmed over a gentle fire, they are set as straight as possible, and laid aside for several days. They are then rubbed over, by means of a piece of flannel, with linseed oil, which produces a polish, and brings off the superfluous bark: they are then bound tight to a straight pole, and kept till next spring, by which time they will be seasoned for use. They are then matched together in due proportions, in two, three, or more parts, according to the desired length, or the opinion of the maker as to the number of pieces of which a rod should be composed. A well-constructed spliced rod of no more than two pieces casts a line with fully as much force, neatness, and accuracy as any other; but it is inconvenient to a traveller, or to any one whose dwelling is not close upon a stream. If the pieces are not ferruled, they must be spliced so as to join each other with great exactness. The principal object to be kept in view in the formation of rods in general is, that they should taper gradually and bend regularly. A frequent defect is their bending too much in the middle, owing to that part not being sufficiently strong.

We have said that the length of a rod is rather a matter of taste than of established rule. It must, however, bear a relation to the size of the river and the nature of the expected capture. A trouting rod is usually made from 12 to 14 feet in length, though some prefer them of greater extent, as giving more command over lakes and spreading pools. It should be made as light as is consistent with strength and durability, as a heavy rod is cumbersome, fatiguing, and unwieldy; and a light one gives a more ready power in casting under hollow banks, or among trees or bushes. For pike and barbel a proper length is 16 feet; for perch, chub, bream, carp, eels, and tench, a shorter rod may be used; and 8 or 10 feet is sufficient for dace, gudgeon, ruff, bleak, &c. The portability of a rod depends of course on the number of joints; but its excellence being almost in the inverse ratio, care must be taken not to sacrifice its goodness merely for the sake of a convenient form.

According to Mr Bainbridge, the best rods are made from ash, hickery, and lance-wood; ash for the bottom piece, hickery for the middle, and lance-wood for the top-joints. If real bamboo can be procured of good quality, it is preferable to lance-wood. Rose-wood and partridge-wood from the Brazils may also be used for the top-pieces. The extreme length of the top-piece is usually composed of a few inches of whalebone. The rings for the reel-line may be made by twisting a piece of soft brass-wire round a tobacco-pipe, and soldering the ends together. They ought to diminish in size as they are made to approach the top, and must form a straight and regular line with each other when the rod is put up for use.

In finishing a rod the usual varnish is copal varnish, or Indian rubber dissolved over a slow fire in linseed oil. It may be stained by a dilution of nitric acid or oil of vitriol. When rods are stored for the winter, after use, they ought to be rubbed over with tallow or salad oil. As few anglers require to make their own rods, we deem it unnecessary to enter into a full detail of a mechanical practice which can only be sufficiently executed by an individual of pro-

Angling. fessional experience. We shall merely mention, that, in addition to the woods already named, elder, holly, yew, mountain ash, and briar, all of which are indigenous to this country, furnish materials to the makers of rods.

As lines may be purchased from the tackle-makers at a cheaper rate than they can be made by an amateur whose time and labour are of value for any other purpose, we shall not here enter into a detail of their formation. The best hair is procured from the tail of a well-grown stallion. Black hair is generally strong, but the colour is not very serviceable. Transparent and almost colourless hair is the most approved; and it ought to be round, regular, and free from blemishes. In the formation of lines each hair in a link should be equal, round, and even, which proportions the strength and prevents single hairs from breaking, and thus weakening the others. Chesnut or brown-coloured hairs are best for ground angling, especially in muddy water. Some anglers stain their lines a pale green for fishing in weedy waters. Black is occasionally used in streams which flow from mosses, and are themselves of an unusually dingy hue.

The following are some of the methods used by anglers for dyeing their lines, whether of hair or gut.

For a pale watery green.—To a pint of strong ale add half a pound of soot, a small quantity of walnut leaves, and a little powdered alum; boil these materials for half or three quarters of an hour, and when the mixture is cold steep the gut or hair in it for ten or twelve hours.

For a brown.—Boil some powdered alum till it is dissolved; add a pound of walnut-tree bark from the branches when the sap is in them, or from the buds, or the unripe fruit. Let the liquid stand till nearly cool, and skim it; then put in the gut or hair, and stir it round for about a minute, or till it appears to have imbibed the desired tint. It ought not to be strongly tinctured, as it is apt to rot when too dark. For a *bluish watery tint* the above ingredients are also used, with the substitution of logwood instead of walnut.

For a yellow.—The inner bark of a crab-tree boiled in water, with some alum, makes a good yellow, excellent for staining tackle used among decayed weeds, the colour of which it closely resembles.

A tawny hue is obtained by steeping hair among lime and water for four or five hours, and then allowing it to soak for a day in a tan-pit. In the absence of other ingredients, both gut and hair may be easily stained by being left for twenty-four hours in strong tea, either with or without a few log-wood scrapings.

The hair to be dyed ought to be selected from the best white. Silken or hempen lines may be tinted by a decoction of oak bark, which is said to add to the durability of these materials.

We shall now proceed to consider the subject in relation to the different species of fish which form the principal objects of the angler's art.

The Salmon. (*Salmo Salar.*)

As the natural history, classification, and characteristic distinctions of fishes will be given at length under the article ICHTHYOLOGY in this work, we shall not here enter into any description of either the structure or habits of the class, but confine ourselves for the present almost entirely to such points as are most essential to the practical knowledge of the angler.

This fine fish delights in large and rapid rivers. It bites best from six in the morning till eleven in the forenoon, and from three in the afternoon till sunset. A moderate breeze is of advantage; and the best months are March, April, May, and June. The salmon is justly regarded by the angler as the king of fish; and when we consider that they occasionally measure four feet in length, and weigh upwards of 70 pounds, we may conceive how difficult a capture and how valuable a prize they sometimes prove. The most successful bait, as well as the most agreeable in the usage, is the artificial fly. This is made in imitation both of dragonflies and butterflies of various kinds; but the principles which we have already endeavoured to establish at the commencement of this article make it unnecessary to describe the natural species. Even those who most warmly advocate the necessity of imitating existing insects in the formation of their lures, admit that the salmon is so capricious as frequently to rise at an artificial fly which bears no resemblance to any natural form of insect life.

The following are the descriptions of six artificial flies which have been found very successful in raising salmon. No. 1 (see Plate XLI. fig. 1) is recommended as a spring fly, and is composed of the following materials: Wings of the dark mottled brown or blackish feather of a turkey; body of orange camlet mixed with a little mohair; and a dusky red or bright brown cock's hackle, plucked from the back where the fibres are longest, for the legs. The hook should be of the same size as represented in the plate; and it has been observed that all large salmon-flies should be dressed upon two or three lengths of gut twisted together, and that the silk in dressing be brought beyond the shank of the hook, and wrapped four or five times round the gut, so that it may not be speedily cut by the sharpness of the steel.[1] This same fly, dressed with the wings of a somewhat brighter shade, and with the addition of a little gold wire or thread wrapped round the body at equal distances, will also serve for a more advanced season of the year. No. 2 (see Plate XLI. fig. 2) is of smaller size, and may sometimes be dressed upon very strong single gut. Any feather of a coppery or dingy yellow colour, if not too coarse in the fibres, will be suitable for the wings; the body is of lemon-coloured mohair, mixed with a small portion of light brown fur or camlet, with a pale dusky ginger hackle over the whole. The chief object to be attended to in dressing this fly is to produce that uniform hue, devoid of gaudy colouring, from which it has received the name of the *quaker fly*. Of No. 3 (see Plate XLI. fig. 3) the wings are made from the plumes of a cormorant, or from the mottled feathers of a dark mallard: the body is of dark sable, ribbed with gold wire, over which a dusky red hackle is thickly wound: the mottled feathers of a drake are used for the tail; and previous to fastening off, a small portion of flos silk should be unravelled and fastened at the extremity of the hook. This fly, though, like the preceding, of a somewhat sombre cast, is frequently used with success in summer. No. 4 (see Plate XLI. fig. 4) belongs to the gaudy class of lures, "which," says Mr Bainbridge, "however fanciful or varied in shade or materials, will frequently raise fish when all the imitations of nature have proved unsuccessful; indeed so fastidious and whimsical are the salmon at times, that the more brilliant and extravagant the fly, the more certain is the angler of diversion." In this, of course, we perfectly agree. The wings of the fly in question are formed of the extreme end of a Guinea fowl's feather, not stripped, but having the fibres remaining on both sides of the middle stem. A blood-red hackle is fastened on with the wings, and so arranged

[1] Bainbridge's *Fly-Fisher's Guide*, p. 96.

as to extend beyond them: the dyed feathers used by military men will suit, if another showy biped, the scarlet maccaw, is not accessible. The green feather which forms the eye of the peacock's tail should be fastened at the head, and left hanging downwards, so as to cover the body for the space of half an inch; and a few filaments of the same part of the feather may be fastened at the tail. No. 5 has the wings formed from the darkish brown speckled portion of a bittern's wing stripped off from the stem: the head ought to be of the same colours as the body, which is formed of the reddish brown part of a hare's fur, and deep copper-coloured mohair; a bittern's hackle is put over the body for legs, and a forked tail is added, made of a pair of single filaments of the same feather as the wings. Of No. 6 the wings are formed of the mottled feathers of a peacock's wing, intermixed with any fine plain dusky red; the best mixture for the body is the light brown inner hair from a bear's skin, sable fur, and gold-coloured mohair; gold twist, a large black cock's hackle, and a red one a little larger, with a bit of deep red mohair for the head. In addition to these, we might enumerate the brown fly, the blue fly, the king-fisher, the prime dun, the great palmer, the golden pheasant, the gray mallard, and many others; but such as are above described will suffice for the purposes of the present treatise. Fig. 6 of Plate XLI. represents an excellent spring fly; and an approved summer kind is shown on the same plate, fig. 5.

It may be stated at once, that so far from imitating nature, the maker of salmon flies can scarcely form them in too unnatural and extravagant a manner. Let him call in the aid of fancy at all times and places, at least in this country; for the cold and cloudy clime of Scotland assuredly furnishes nothing resembling the lures most frequently and most successfully used. The superabundant use of gold and silver wire ought, however, to be avoided, as it not only causes the fly to sink too much in the water, but prevents its being neatly or lightly thrown. Spring flies for salmon are usually made of a larger size, though not so gaudily dressed as those of summer.

A salmon rod is generally proportioned to the size of the river which the angler frequents; but it ought not to be less than 15 feet in length. The reel ought to be large enough to contain 80 or 90 yards, so as to admit of abundance of line being given out when required; for many fish, when struck, run out to a great distance, and with such immense rapidity as to prevent the possibility of the angler's moving in the proper direction with sufficient quickness. A salmon, for the most part, darts violently up the stream; and, as the command and direction of the fish is more easily kept with a short than a long line, it is advisable to prevent his getting too far ahead, by keeping the rod well back in the opposite direction, and by running towards him along the margin of the stream. When he gains the head of the current, a salmon frequently throws himself several times out of the water, on which occasions the angler must yield him freely a little of the line; but during his general and less violent manœuvring, he will of course be the sooner exhausted the more firmly he is held. When he appears to be making for some safe haunt or secret sheltering place, the great object is to turn him towards safer ground, either by relying on the soundness of the tackle, or, if he proves very powerful as well as very obstinate, then a pebble or two may be thrown, so as to fall a little in advance of his position, and he will probably turn himself round. Some fish become very sulky, and will lie after being hooked, for a long time, motionless near the bottom. In this case also the pebbles must be had recourse to; for the more a fish is kept in motion, the sooner he becomes exhausted. When he begins to show his side, and exhibits other unequivocal symptoms of exhaustion, a favourable landing-place should be looked for; and when the proper time arrives, which can only be learned by the (sometimes dearly bought) lessons of experience, then is he to be drawn by degrees to the gravel bank, or the gaff applied, and the prize secured.

When feeding, salmon are usually found at the foot of a strong stream, terminating in an eddy or whirlpool. "And first," says our father Walton, "you shall observe that usually he stays not long in a place, as trouts will, but, as I said, covets still to go nearer the spring-head."

When the water is either too much discoloured for the use of the artificial fly, or, running into the opposite extreme, becomes (especially in very still weather) too clear and bright, salmon may be successfully angled for with the worm. In this case trolling tackle is sometimes used.

In trolling with minnow or other small fish, the foot lengths ought to be about three yards long, and furnished with one or two swivels, to prevent the line from twisting, as well as to enable the bait to play freely. A lead or shot proportioned to the strength of the stream should be fastened to the line, about a foot above the bait. The top of the rod should be stiffer than that used for fly-fishing; and when the hook is baited, it ought to be thrown first across, and then drawn up the stream.

The spawning process, with salmon, commences late in autumn, and continues through the winter months, the exact period varying with the sexual condition of individual pairs. The ova are hatched after the lapse of from 90 to 120 days, the period depending on the temperature of the stream; that temperature varying according to the locality, or the character of the season. The young usually remain in their native river (under the name of *par*) for a couple of years, after which they are transmuted into *smolts*,—small fishes of a silvery hue, with but slight vestiges of the coloured spots and bars by which they had been previously characterised. In this state they make their way in spring into the sea, where the rapidity of their growth is extraordinary, and has not yet been explained or accounted for. In a few months (sometimes even in a few weeks) they again seek their native streams, having, during a very short sojourn in the sea, increased from the weight of a few ounces to that of several pounds. Without discussing the distinctions of salmon trout, whitlings, grilse, and salmon, suffice it here to say, that all these migratory fish, usually characterised by their small number of spots, their silvery colour, and the superiority of their flesh, may be angled for with much larger and more gaudily plumed flies than those used in the capture of river-trout.

The Common Fresh-water or River Trout. (*Salmo Fario.*)

This species varies greatly in size and colour, in accordance probably with the nature and abundance of its food, the strength and depth of the river in which it occurs, and the physical properties of soil and climate. Fish seem, more than most animals, to depend on peculiar and unappreciable circumstances, for the full and characteristic development of their characters; and they consequently exhibit great contrariety of aspect among individuals of the same species. If a canal or reservoir, or any other great accumulation of water, is formed by the hand of man, where the hand of nature had from time immemorial recognised only some small and solitary streamlet, the lapse of even a few months produces large and heavy fish, where none but trouts of the most trifling size had ever been seen before. The writer of these observations kept a minnow little more than half an inch long in a glass tumbler for a period of two years, during which time there was no perceptible increase in its dimensions.

Had it continued in its native stream, subjected to the fattening influence of a continuous flow of water, and a consequent increase in the quantity and variety of its food, its cubic dimensions would probably have been 20 times greater; yet it must have attained, prior to the lapse of a couple of years, to the usual period of the adult state. In regard to birds and quadrupeds, the individuals of the same species are not distinguishable from each other by any peculiarities either of form or colour, at least within the limits of a restricted locality; but it appears to be otherwise with several species of fish, more especially trouts. Those of the Clyde and Tweed, although both rivers draw their primary sources almost from the same mountain, present a constant and well-marked difference in their external aspect; and a corresponding dissimilarity exists among the characteristic varieties of almost every river and lake in Scotland; " which I tell you that you may the better believe that I am certain, if I catch a trout in one meadow he shall be white and faint, and very like to be lousy; and as certainly, if I catch a trout in the next meadow, he shall be strong, and red, and lusty, and much better meat. Trust me, scholar, I have caught many a trout in a particular meadow, that the very shape and the enamelled colour of him hath been such as hath joyed me to look on him; and I have then with much pleasure concluded with Solomon, ' Every thing is beautiful in his season.' "[1]

No fish affords the angler more varied or more constant sport than the trout. For nine months in the year, under favourable circumstances, fly-fishing may be practised for it with success. Westerly and southerly winds are the most favourable, especially in spring; but during warm and cloudy summer weather, the point from which the wind blows is of slight consequence. " He who considers the wind," says Solomon, " will never sow;" and the same remark is not inapplicable to angling. Whoever desires to become a successful practitioner in the art, must angle in all weathers, and under every variety of circumstances, however unpropitious the prospect may be. Trout are generally supposed to rise more freely during a dark and lowering day, following a clear bright night, as brilliant moonshine detains them in their lurking-places; and on the ensuing day they are consequently more inclined for food. On the other hand, after a gloomy or darkish night they are less easily tempted, having glutted themselves with moths and other nocturnal insects, which, during the summer months, are abundant on the waters. In throwing the line the angler should endeavour to make his gear fall as lightly as possible on the surface, and his flies should drop opposite, or somewhat above his own position, and then be played gently and neatly downwards and across the stream. When a trout is seen to rise at a natural fly or other insect, the artificial one should be offered him by being thrown, not directly over him, but about a yard higher up the stream; and, if he is inclined to rise again, he will probably meet it half-way. When a fish, on being hooked, descends beneath the surface, and struggles in the depths below, it is a pretty sure sign that he is well secured; but when he flounders on the surface, or leaps occasionally into the air, more care is necessary, as in that case the hook will frequently be found to be only skin-deep. In playing and landing a large trout the same precautions are necessary as in salmon-fishing, although in regard to smaller fish, if the angler is standing in the centre of a stream, and finds it inconvenient to wade frequently ashore, a few additional turns will exhaust the capture, which may then be drawn rapidly and steadily to the hand, and secured by a firm grasp behind the gills. We have frequently practised a summary method of landing even tolerably sized fish; which, though it cannot always be effected, is, when possible, a great saving of time. If, from the moment the trout is struck, he is prevented from redescending in such a manner that the upper part of his head and eyes are retained above or on a level with the surface, he will for the space of a good many seconds be so much astonished as to be incapable of any active exertions, and will frequently allow himself to be drawn in that position, and without resistance, straight ashore.

The following flies are in repute among anglers. The *black gnat* appears about the end of April. The body is formed of a black strip from an ostrich feather, and ought to be dressed thick and short; the wings of a pale starling's feather, or dressed as a hackle with a pale dun.

The *March brown* or *dun drake* is frequently visible by the middle of March. The wings are made from the mottled feathers of a partridge's tail, and the body of hare-ear fur, intermixed with a little yellow worsted; a grizzled hackle for legs.

The *hazel fly* is of a round form, and difficult of imitation. It is a killing fly in May and June, especially where bushes abound. The body is composed of ostrich harl of two colours, black and purple twisted together; the wings of the sandy-coloured feathers from under the wings of a thrush, or the reddish plumes of a partridge's tail; a bluish hackle, twisted pretty full, serves both for the under wings and legs.

The *great dark dun*, according to Mr Bainbridge, is one of the earliest flies which appear upon the water, and may be used in February, if the weather is mild. The wings are formed from the dun feathers of a mallard's wing; the body of mole-fur, mixed with a little dark brown mohair; a dark grizzled hackle for legs. Salmon frequently rise at this fly, which may be used with success early in the morning during the whole fishing season.

The *wren's tail* has no wings: the body is of sable fur, with a little gold-coloured mohair, and a feather from the tail of a wren.

The *grouse hackle* is also wingless: the mixture for the body is dark olive, dusky yellow, and a little gold-coloured mohair. It is formed of a fine mottled grouse's feather of a reddish brown, running a little dusky towards the butt-end of the stem, and the downy portion, if any, plucked away.

The *stonefly* is found along the edges of streams, and is a favourite article of food among trout. It is a species of Phryganea, and springs from a caddis or aquatic larva. The wings lie flat, and are imitated by the mottled feather of a hen-pheasant or peahen. The body is composed of dark brown fur from a bear's skin, or the deeper part of a hare's ear, mixed with yellow camlet or mohair; a longish grizzled hackle is wrapped under the wings.

The *mealy brown* or *fern fly* is excellent for grayling in May. Its wings should be formed from the under part of a throstle or fieldfare's wing, especially from such feathers as have a yellowish tinge. Its body is of a dusky orange, from the light brown fur of a fox's breast, with a pale dun hackle for legs.

The *orange fly* has four wings made of the blue feather of a mallard-teal. The head is of the dark fur from a hare's ear; the body gold-coloured mohair mixed with orange-camlet and brown fur, a small blue cock's hackle for legs. This is said to be an alluring fly to young salmon.

[1] Walton's *Complete Angler*, p. 128, edit. 1823.

The *hare's ear* is chiefly used as a drop-fly. The wings are from the light part of a starling's wing feather, and the body of dark hare-ear fur. According to Daniel, when the streams are deep, the same body winged with a rail-wing's feather and a red hackle is very killing during the summer season.

The *yellow dun* is used in the morning and evening during the months of April and May, and again in September. The body is made of yellow yarn unravelled, or with marten's fur, and mixed with a little pale ash-coloured fox-cub fur; the wings are formed upright, from the under part of a snipe's wing, with a pale dun hackle for legs.

The *hawthorn fly* is in use from the middle of April to the end of May, from ten o'clock till three. It has transparent wings, which may be imitated with the palest feather of a snipe or mallard's wing; horn shavings, or the membranous substance found in the core of an apple, serve the same purpose; the body is of black ostrich harl, with a black hackle for legs.

The *summer dun* has a thicker form than most of the dun flies, and is dressed upon a short-shanked hook. Mole-fur ribbed with ash-coloured silk is employed for the body; the wings are from the wood-pigeon, with an ash-coloured hackle for legs.

The *black-hackle fly* is an approved lure during warm weather, early in a summer morning. The body is formed of a thin-dressed ostrich harl, cut close; the wings, four in number, are from the pale feather of the starling's wing.

The *red spinner* is used as a dropper. The wings are formed of the grayish feather of a drake, tinged with reddish yellow; the body a red hackle, with a twist of gold. This fly is eagerly taken by chub in the evenings of July.

The *little yellow May* or *willow fly* resembles the green drake, on a small scale. The body is formed of yellow fur from the marten's neck, or of yellow worsted unravelled, and mixed with a very small portion of hare-ear fur; the wings are of mallard's feather dyed yellow. This fly appears early in May, and may be used till the appearance of the green drake, of which it is the usual precursor.

The *brown dun* is made of otter's fur mixed with lemon-coloured mohair; the wings are from the fieldfare, with a ginger hackle for legs. This is an excellent fly towards the approach of twilight.

The *green drake* or *May fly* appears about the second or third week of May, and continues about a month. The body is made of hog's down, or light bear's hair, intermixed with yellow mohair; or of barbers' yellow silk only, warped with pale flos silk, and a small strip of peacock's harl for the head: a bittern's hackle is the best imitation of the legs and dark stripes of the body; with the long hairs of the sable or polecat for the tail. The rayed feathers of a wild mallard, dyed of a greenish yellow, suffice for wings.

The *blue blow* is a very small fly used during the summer months, and for the first fortnight in August. It is made of a lapwing's top, or any dark blue fur, dressed on a very small hook. The wings are of thistle-down or bluish-white hackle.

The *black midge* is also a small species, the body of which is dressed with brownish-black silk, and a blue cock's hackle. It is taken freely after a shower in the summer evenings.

The *gray drake* follows the green of the same name, although they sometimes occur together. It is an excellent afternoon fly for large trouts. The body is formed of a dirty-white ostrich harl, dressed with flesh-coloured silk, and ribbed with a dark-grizzled cock's hackle; the head is made of peacock's harl, like that of the green drake; the wings from a mottled mallard feather, or that of a mallard-teal, and the tail of sable or polecat's hair.

The *cinnamon fly* has four wings, large in proportion to the body. They are made from the pale reddish-brown feathers of a hen, dressed full; the body of dark brown fur, with a ginger hackle for legs. This fly, according to Mr Bainbridge, is excellent for the Welsh rivers during the months of August and September.

The *sand fly* forms an excellent lure, and may be very generally used from April to September. The wings are formed from the sandy-coloured feathers of the landrail's wing, with a ginger hackle for legs; and the bright sandy-coloured fur from the neck of a hare, mixed with a little orange mohair for the body. If dressed as a hackle, the feathers from under the thrush's wing resemble the natural hue of the wings of the insect.

The *great black ant* makes its appearance in sultry weather, from the middle of June to the latter end of August. The wings are made of the pale-blue feathers from beneath a snipe's wing, or from a tomtit's tail. The body is of black ostrich harl, made thick towards the tail and beneath the but of the wings; the legs of a reddish-brown hackle.

The *great red ant* is nearly contemporaneous with the preceding, which it resembles in size and form. The wings are made of a light starling's feathers; the body of gold-coloured mohair, or copper-coloured peacock's harl, with a ginger hackle for legs.

Among the preceding flies will be found some which will assuredly suit for any river, or for any period of the fishing season. The angler who places implicit confidence in the generally received opinion, that in every stream, and at each season, there is one particular fly in much more special request than any other, will do well to prepare for an unknown river, by making ready a couple of lines, each with three flies all of different kinds. For example, a March brown at the end of the line, a dun hackle, with a lighter or darker body to suit the weather or complexion of the stream, for the first dropper, and a red hackle with peacock body for the second dropper; or, *2dly*, a sand fly at the end, with a grouse hackle or wren's tail, with orange body, for the first dropper; and a pale yellow or cream-coloured hackle over a bluish body, or one of the ant flies, as the second dropper. These are promising flies for most seasons of the year, though, like the others, they require to be changed according to the circumstances of time and place, or the varying caprices of the finny tribes.

As night fishing is a favourite amusement with many anglers, we shall describe a few of the flies in most repute for the practice of nocturnal sport.

The *white moth*, with wings made from the feathers of a white owl, the body of white ostrich harl, with a white cock's hackle over it.

The *brown moth* is winged from the feathers of a brown owl, or the back feathers of a brown hen; the body is of dark bear's hair, covered with a brown cock's hackle.

The *mealy cream* is made from the tawny feathers of a white owl for the wings, with some soft fur of the same colour, and a pale yellow hackle for the body.

The following selection has been recommended by an experienced angler, in relation to the alleged succession of flies during several of the principal months of the fishing season. *1st*, For March, a dun fly, made of dun wool, and the feathers of a partridge wing; or the body made of black wool, and the feathers of a black drake: *2d*, For April, a stonefly, the body made of dark wool, dyed yellow under the wings and tail: *3d*, For the beginning of May, a ruddy fly, made of red wool, and bound about

with black silk, with the feathers of a black cock hanging dangling on his sides next his tail: 4*th*, For June, a greenish fly, the body made of black wool, with a yellow list on either side, the wings taken off the wing of a buzzard, bound with black broken hemp: 5*th*, The moorish fly, the body made of dusky wool, and the wings of the blackish mail of a drake: 6*th*, The tawny fly, in great repute till the middle of June; the body made of tawny wool, the wings contrary, one against another, composed of the whitish mail of a white drake: 7*th*, For July, the wasp fly, the body made of black wool, cast about with yellow silk, and the wings of drakes' feathers: 8*th*, The steel fly, approved in the middle of July; the body made with greenish wool, cast about with the feathers of a peacock's tail, and the wings made of those of a buzzard: 9*th*, For August, the drake fly, the body made with black wool cast about with black silk, the wings of the mail of a black drake, with a black head.

When rivers are very low and clear, from a long continuance of summer drought, it has been recommended to use a pair of wings made from the feather of a landrail, or the mottled feather of a teal, with a well-cleaned gentle fixed upon the hook. During a similar condition of the water, even when no wind is stirring, and the sun shining in its greatest lustre, trouts may be taken with a small *wren's tail*, *grouse*, *smoky dun*, or *black hackles*, the angler fishing straight down the water, by the sides of streams and banks, and keeping well out of sight, with as long a line as can be neatly managed, and the foot-lengths very fine. At these times the fish may be often seen with their dorsal fins above water, and with skilful management may be made to snap at the above-named flies. When one is hooked, the rest dart off; but if the angler keeps concealed, they will return again in a very short time; and thus several fish may be taken even in summer from the clearest pools. Another plan has also been recommended as likely to prove successful when the weather is bright and the water low: Take a line of about a yard in length, and fix it to a short, stiff rod, and having baited the hook with a natural fly, such as the stonefly, or the gray or green drake (Ephemeræ), drop it between bushes over steep hollow banks, or under the projecting roots of trees.

In fishing a river with which the angler has no previous acquaintance, the most approved practice is to try the eddies which are frequent at the corners of streams, and where the circular movement of the current throws out a frequent sustenance for the finny race. There the larger trout often lie; and it must consist with the experience of every angler, that an excellent capture is sometimes made repeatedly from some small spot behind or beside a particular stone, where from day to day one well-sized fish seems to succeed another in the favourite feeding ground. In this knowledge of peculiar localities consists the chief advantage of a previous acquaintance with the water. The smaller fish are found in most abundance in the widely spread and shallow streams, as well as in the extended parts of pools of no great depth. As a general rule, the angler may be advised to fish with the wind on his back and the sun in front, which not only gives him a greater command of his line, but prevents himself or his shadow from being so distinctly perceived. A strict adherence, however, to this plan is by no means advisable, as the angler's position in relation to sun and wind must frequently vary with the natural course of the river, the obstruction of overhanging wood, and the greater or less command of pool and stream presented by the varying form of the adjoining shore.

As *bait-fishing* for trout, though regularly followed by some, is less generally admired and practised than the more elegant use of the artificial fly, fewer words will suffice. When the streams are swollen and discoloured, fine trout may be taken with a running line without float, and so leaded that it shall touch the ground without resisting the force of the stream. The lead should be fixed about eight or ten inches above the hook; and the best baits are well-scoured earthworms. The dew, the garden, and the lob worms are one and the same in species, although they vary considerably in form, size, and colour, according to age, and season, and the nature of the soils. The lobworm, according to Daniel, is of two sorts, the old, *knotted*, the young, without knots, which some for distinction call *maiden lobs*, and others *red* worms. The latter kind, with a red head, a streak down the back, and a broad tail, are the most esteemed. By some they are called squirrel-tails. These and other worms, it need scarcely be observed, are easily obtained in fields and gardens, especially where there has been any recent mixture of vegetable or animal remains. They may be preserved for a considerable period, and even improved in their texture and condition, by being kept in damp moss, changed from time to time, and occasionally wetted with a little new milk. In dry weather, when worms are difficult to be obtained, they may be procured by emptying a few buckets of water in situations where they were known to occur during a moister season. The brandling worm is streaked from head to tail in alternate circles of a red and yellow hue, and is darker at its anterior than posterior portion. They occur in old dunghills, in heaps of rich vegetable mould, and among rotten tan bark. They have this advantage over the others, that they may be used without preparation or scouring. Though the choice of worms does not seem a very suitable subject for poetry, it has been thus versified by Mr Gay in the *Rural Sports*:

> You must not every worm promiscuous use,
> Judgment will tell thee proper baits to choose:
> The worm that draws a long immod'rate size,
> The trout abhors, and the rank morsel flies;
> And if too small, the naked fraud's in sight,
> And fear forbids, while hunger does invite.
> Those baits will best reward the fisher's pains,
> Whose polish'd tails a shining yellow stains;
> Cleanse them from filth, to give a tempting gloss
> Cherish the sullied reptile race with moss;
> Amid the verdant bed they twine, they toil,
> And from their bodies wipe their native soil.

The preceding rhymes apply chiefly to the kind called gilt-tails. *Gentles* are the larvæ of different kinds of carnivorous winged flies. They may be kept in a mixture of oatmeal and bran, and are readily produced in a piece of liver, or any other flesh or fish, exposed in an earthen vessel to prevent their escape when grown to a proper size. All kinds of maggots, as well as those called gentles, serve admirably for the more delicate kinds of bait-fishing. The caddis worms, before alluded to as the larvæ of the Phryganea or stonefly, when taken out of their cases, are a favourite bait for trout; and different kinds of grasshoppers are likewise used with great success. The creeper or water cricket, an aquatic larva, found under stones within the water-mark, ought also to be attended to by the natural bait-fisher.

The palmer worms or wool beds are the hairy caterpillars of certain nocturnal moths. Though refused by almost all birds except the cuckoo, they are swallowed by trouts, and may be preserved alive for many weeks in a box with damp earth, strewed over with the leaves of the tree or bush on which the species was observed naturally to feed.

The young brood of wasps and bees are useful to the angler; and for eight or ten days after their first appearance in summer there is no better or more killing bait

than a small reddish beetle called the *bracken clock* in the north of England, the *Melolontha horticola* of naturalists. Salmon roe is greatly lauded by Barker, who appears to have been the first to discover its merits. "I have found an experience of late which you may angle with, and take great store of this kind of fish. First, it is the best bait for trout that I have seen in all my time, and will take great store, and not fail if they be there. Secondly, it is a special bait for dace or dare, good for chub, or bottlin, or grayling. The bait is a roe of a salmon or trout. If it be a large trout, that the spawns be any thing great, you must angle for the trout with this bait as you angle with the brandling, taking a pair of scissors and cut so much as a large hazel-nut, and bait your hook; so fall to your sport,—there is no doubt of pleasure. If I had known it but twenty years ago, I would have gained a hundred pounds only with that bait: I am bound in duty to divulge it to your honour, and not to carry it to my grave with me. I do desire that men of quality should have it, that delight in that pleasure. The greedy angler will murmur at me, but for that I care not."

Many kinds of pastes are prized by the bait-fisher. They may be used for chub, carp, and bream in September and during all the winter months, and may be made up about the size of a hazel-nut; if for roach and dace, the bigness of a pea will suffice. All pastes are improved by being mixed up in the making with a little cotton wool, which makes them firmer and more tenacious, and hang better on the hook. They suit well for fishing in quiet places, with a small hook and quill float. We shall here subjoin a few recipes for the making of fishing pastes, which, although we introduce them under the head of the river-trout, may be regarded as equally efficacious in the capture of other kinds of fish.[1]

Minnow-fishing for trout is a favourite pastime with many anglers, and the process is one by which very large fish are frequently captured. The tackle used resembles that for salmon, but is lighter and finer, with a single line of gut at the bottom. The hooks vary in size according to the general dimensions of the trout angled for; and the middle-sized and whitest minnows are the most esteemed. The following were Walton's directions for baiting, with a view to this department of the sport. Put your hook in at his mouth and out at his gill; then having drawn your hook two or three inches beyond or through his gill, put it again into his mouth, and the point and beard out at his tail, and then tie the hook and his tail about very neatly with a white thread, which will make it the apter to turn quick in the water: that done, pull back that part of your line which was slack when you did put your hook into the minnow the second time; I say, says Walton, pull that part of your line back so that it shall fasten the head, so that the body of the minnow shall be almost straight on your hook: this done, try how it will turn by drawing it across the water or against a stream; and if it do not turn nimbly, then turn the tail a little to the right or left hand, and try again, till it turn quick. We may add, that the practice of fishing with the artificial minnow is justly discarded by all judicious anglers. For representations of the minnow tackle, and hooks baited, see Plate XLI., fig. 12, 13, and 19.

The Great Lake Trout. (Salmo Ferox.)[2]

It appears that the gray or great trout of the British fresh-water lakes, though never described or characterized as a distinct species, has at various times excited the attention of ichthyologists. Trout of enormous dimensions are mentioned by Pennant as occurring in the Welsh lakes; and Donovan gives Loch Neagh in Ireland as another locality. Very large trout have been killed in Ullswater in Cumberland, and still larger in Loch Awe in Argyllshire. The late Mr Morrison of Glasgow claimed the merit of discovering these fish in the last-named locality about 60 years ago; and the largest recorded to have been killed there weighed 25 pounds. Mr Lascelles, a Liverpool gentleman, has also of late years been equally assiduous and successful in their capture; and it appears that any persevering sportsman is almost certain, with the proper tackle, to obtain specimens in Loch Awe, of this great fish, weighing from 6 to 12 pounds. The largest we have lately heard of weighed 19¼ pounds. It is said to be by far the most powerful of our fresh-water fishes, exceeding the salmon in actual strength, though not in activity. The most general size caught by trolling ranges from 3 to 15 pounds: beyond that weight they are of uncommon occurrence. If hooked upon tackle of mode-

---

[1] *Red paste* may be made with a large spoonful of fine wheat-flour, moistened with the white of an egg, and worked with the hands until tough. A small quantity of honey or loaf-sugar finely powdered must be added, together with some cotton-wool spread equally over the paste when pressed flat in the hand; it must be well kneaded, to mix the cotton thoroughly; colour it with a little vermilion. A small piece of fresh butter will prevent it from becoming hard, and it will keep good a week. *White paste* may be composed of the same ingredients, omitting the vermilion; and *yellow paste* in like manner, with the addition of turmeric.

Salmon paste.—Take one pound of salmon-spawn in September or October; boil it about 15 minutes, then beat it in a mortar until sufficiently mixed, with an ounce of salt and a quarter of an ounce of saltpetre; carefully pick out the membrane in which the spawn is contained, as it is disengaged from it; when beat to a proper consistence, put it into gallipots, and cover it over with bladders tied down close, and it will keep good for many months.

Various oils were formerly in great repute among anglers for rubbing over their baits, but as we believe their beneficial effects were entirely imaginary, we shall not occupy our pages by their repetition. A single extract from Izaak Walton will suffice. "And now I shall tell you that which may be called a secret: I have been a-fishing with old Oliver Henley, now with God, a noted fisher both for trout and salmon, and have observed that he would usually take three or four worms out of his bag, and put them into a little box in his pocket, where he would usually let them continue half an hour or more before he would bait his hook with them. I have asked him his reason, and he has replied, 'he did but pick the best out, to be in readiness against he baited his hook the next time.' But he has been observed, both by others and myself, to catch more fish than I or any other body that has ever gone a-fishing with him could do, and especially salmons; and I have been told lately, by one of his most intimate and secret friends, that the box in which he put those worms was anointed with a drop, or two or three, of the oil of ivy-berries made by expression or infusion; and told that by the worms remaining in that box an hour, or a like time, they had incorporated a kind of smell, that was irresistibly attractive, enough to force any fish within the smell of them to bite." We need scarcely remind the reader of the "Complete Angler," that that admirable work is of higher value for the manner in which the subject is discussed, and the beautiful accessories of pure style, poetical sentiment, and picturesque illustration, than for the amount of direct practical information which it conveys. The simplicity and goodness of Izaak Walton's nature seem to have induced a greater degree of credulity than was always consistent with an accurate perception of the truth, and hence every chapter abounds with statements which could not pass current in these more critical days. As a useful work in relation to the mere angler, it cannot be said to hold a high rank, although it must ever delight the general reader, and all who desire to refresh themselves by "the pure well of English undefiled."

[2] We are indebted for the principal materials of the following account of this interesting fish to a manuscript of Sir William Jardine's, with which we have been kindly favoured by the author. It forms part of a series of *Memoirs on British Fishes*, which that assiduous naturalist has been for some time past preparing for the press.

rate strength, they afford excellent sport; but the general method of fishing for them is almost as well adapted for catching sharks as trout; the angler being apparently more anxious to have it in his power to state that he had caught a fish of such a size, than to enjoy the pleasure of the sport itself. However, to the credit of both parties, it may be stated, that the very strongest tackle is sometimes snapped in two by its first tremendous springs. The ordinary method of fishing for this king of trouts is with a powerful rod, from a boat rowing at the rate of from three to four miles an hour, the lure a common trout from four to eight inches in length, baited upon six or eight salmon hooks, tied back to back upon strong gimp, assisted by two swivels, and the wheel-line coarse and strong. Yet all this, in the first impetuous efforts of the fish to regain its liberty, is frequently carried away for ever into the crystal depths of Loch Awe!

When in their highest health and condition, and indeed during the whole of the time in which they are not employed in the operation of spawning, these fish will scarcely ever rise at a fly. At these periods they appear to be almost entirely piscivorous; so, with the exception of night lines, baited also with trout, trolling is the only advisable mode of angling for them. The young, however, rise very freely at ordinary lake-trout flies, and are generally caught in this way from one to one and a half pound weight. They occur abundantly near the outlet of the lake.

These great trout are found in Loch Shin, Loch Assynt, Loch Loyal, and other northern lochs. We have there trolled for them successfully with salted sprats, the bright silvery lustre of which seemed attractive in those dark waters. Their spawning period corresponds to those of salmon, that is, it commences in autumn, and continues through the earlier portion of the winter; and at this time their instinctive tendencies are so far changed, that they will rise eagerly at large and gaudily dressed salmon-flies, and may be either angled for from the banks, or trolled with a cross line. They spawn in rivers, but do not ascend so high as either salmon or sea-trout, and they never descend either into or towards the salt water, although an occasional straggler has been taken in the Awe, at some distance down the river. In Loch Shin, they ascend the streams which flow into the loch, but are not known to enter that which flows from it. When in good season, and in their strongest condition, they appear to roam indiscriminately through every part of the loch, though there are certain spots which may be more depended upon than others, and where an experienced angler will have little difficulty in hooking one of these fine fish. To their great strength we may observe that they add unequalled rapacity; and after attaining to the weight of three or four pounds, they appear to feed almost exclusively on smaller fish, and do not spare even their own young. A small trout of this species, not weighing more than 1½ lb., will often dash at a bait not much inferior to itself in size; and instances are recorded of larger fish following with eager eye, and attempting to seize upon others of their own kind after they had been hooked and were in the act of being landed by the angler. It is probably on account of this strong manifestation of a more than usually predaceous habit, that Sir William Jardine has named the species *salmo ferox*.

When in perfect season, and full-grown, it is a very handsome fish, though the head is always too large and long to be in accordance with our ideas of perfect symmetry in a trout. The body is deep and thickly formed, and all the members seem conducive to the exercise of great strength. The colours are deep purplish brown on the upper parts, changing into reddish gray, and thence into fine orange-yellow on the breast and belly. The whole body, when the fish is newly caught, appears as if glazed over with a thin tint of rich lake-colour, which fades away as the fish dies, and so rapidly, that the progressive changes of colour are easily perceived by an attentive eye. The gill-covers are marked with large dark spots; and the whole body is covered with markings of different sizes, and varying in amount in different individuals. In some these markings are few, scattered, and of a large size; in others they are thickly set, and of smaller dimensions. Each spot is surrounded by a paler ring, which sometimes assumes a reddish hue; and the spots become more distant from each other as they descend beneath the lateral line. The lower parts of these fish are spotless. All the fins are broad, muscular, and extremely powerful; and it is from the number of their bony rays that the specific characters which distinguish this species from the common trout (*salmo fario*) are the most easily and accurately evolved. The dorsal fin is of the same colour with the upper part of the fish; it is marked with large dark spots, and contains fifteen rays, which number exceeds by three that which characterizes the common trout. The caudal fin is much larger and more fleshy. The pectoral, ventral, and anal fins, are very muscular on their anterior edges, and of a rich yellowish-green colour, darker towards their extremities. They contain respectively 14, 10, and 12 rays, whereas the numbers in the corresponding fins of the common trout are 13, 9, and 11. The tail is remarkable for its breadth and consequent power. In adults it is perfectly square, or might even be described as slightly rounded at its extremity: in the young it is slightly forked, and appears to fill up gradually as the fish advances in age. In the common trout, on the contrary, the forked shape of the tail is a permanent characteristic.

The flavour of this great lacustrine species is coarse and indifferent. The colour of the flesh is orange-yellow, not the rich salmon-colour of a fine common trout in good season. The stomach is very capacious, and on dissection (differing singularly in this respect from the salmon) is almost always found gorged with fish.

We have bestowed a somewhat lengthened notice on the species above described; but we doubt not that the obscurity of the subject will not only plead our excuse, but render the information now given highly acceptable both to the sportsman and the naturalist. It is certain that a more attentive examination of the finny tribes which inhabit our lakes and rivers would bring to light several new species, and more clearly illustrate the history of others which are still involved in darkness.[1]

The gigantic species of the Swiss lakes, one of which,

[1] Mr Lascelles once killed two trouts in Loch Laggan, which weighed 12 pounds each. These were probably of the same species with the great trouts of Loch Awe. In that magnificent chain of English lakes of which Windermere is the chief, and which includes Grassmere and Rydal, we think the species not synonymous with the *salmo ferox* of Jardine. The lake trouts, properly so called, of these beautiful waters, when full-grown, seem to range from three to five pounds, and have in one or two rare instances been taken of the weight of six and even eight pounds. Those of Ullswater, again, which does not belong to what we have denominated the Windermere chain, correspond more nearly in size and other characters with the species found in the lakes of the Scottish Highlands. We would particularly recommend to the attention of sportsmen the great fresh-water river trout, or bull trout as we believe it is sometimes called. This is regarded by some anglers as an aged or overgrown individual of the ordinary kind (*salmo fario*); and by others, especially when found in the autumn, as a lake trout which had left its more usual haunts for the purpose of spawning. The accuracy of the latter opinion is, however, interfered with by the occasional occurrence of this variety in such unambiguous situa-

killed in the lake of Geneva, weighed 67 pounds, seem closely allied to those of Loch Awe, Ullswater, &c. Though equal to salmon, both in size and strength, they differ in their habits from those fish, and do not appear at any time to seek the waters of the ocean. Indeed their existence in the lake of Constance, the available communication of which with the sea is cut off by the falls of Schaffhausen, demonstrates their independence of saline waters. It does not appear, from any information which has reached us on the subject, that these great continental lake-trouts ever rise at the artificial fly.

In Loch Craggie there is a finely formed and beautiful variety of the common trout, varying in its matured condition from one and a half to three pounds in weight. It affords excellent sport to the angler fishing from a boat a few yards off the deeper parts of the shores. They rise freely to small salmon or sea-trout flies, dressed after the model of a gray or green drake.

The rich and varied supply of all kinds of tackle, which may be obtained in the shops of the principal dealers in our larger cities, induces us to abstain from any description of the different hooks employed in minnow and other bait-fishing, as such details are not very intelligible without the aid of numerous engravings. More knowledge will be gained by a few minutes' inspection of the articles themselves in the hands of an intelligent workman, than can be conveyed by the most elaborate treatise on the subject.

Having described the characteristic modes of angling for salmon and trout, the two species which so greatly surpass all the others in the amusement yielded to the angler, we shall now proceed to a briefer consideration of some of the remaining subjects of our sport.

The Char or Case Char. (*Salmo Alpinus.*)
The Torgoch or Red Char. (*Salmo Salvelinus.*)

These fish, which, in a culinary point of view, are deservedly the most highly prized of all the permanently freshwater species, are scarcely attainable by the angler's skill. Of late years they have risen more freely than in former times in the meres of the north of England; but the capture of a char by rod and line is still regarded as an uncommon occurrence. They appear to retire during the warmer months to the deepest of the still waters, as the fishermen engaged in throwing their nets for pike, perch, and trout, over the very grounds where, during the colder season of the year, the char abound, never catch any of these fish in summer. Although a good deal has been written upon the subject, it does not appear that the distinctive history of the two species above named has been as yet made out. Both the case char and the red char are found in Windermere; and the principal distinction in their habits and history consists in this, that the former ascends the rivers, where it spawns about Michaelmas; whereas the latter deposits its ova along the shores of the lake, and not till the end of December or the beginning of the year. In angling for char the same flies may be used as those best adapted for the smaller-sized lake-trouts; and as the latter occur wherever the former is found, the sportsman has the better chance of making amends for the probable disappointment which will attend his pursuit of the one, by a more successful capture of the other.

The Grayling. (*Salmo Thymallus.*)

This fish loves the clear streams of mountainous countries. It is common in Lapland, where its intestine is used as rennet, along with rein-deer milk, in the formation of cheese. It is a bold and sportive fish, but more tender in the mouth than the trout. It rises well to the camlet fly, and to several of the other small-sized trout-flies. We killed it readily in Switzerland with a moorfowl wing and hare-ear body. They may also be taken with the caddis worm and other ground baits. According to the Rev. Mr Low, the grayling is frequent in the streams of the Orkney Islands, though very rare in the rivers of the mainland of Scotland.

The Pike. (*Esox Lucius.*)

This "fell tyrant of the liquid plain" is not regarded as indigenous to the waters of Britain, but is said to have been introduced in the time of Henry VIII. That it was well known in England at an earlier period is however evident, both from the book of St Alban's, printed by Wynken de Worde in 1496, and from the account of the great feast given by George Nevil, archbishop of York, in the year 1466. There is in truth no evidence either of its non-existence in this country at a remote period, or of its importation during comparatively recent times.

The voracity of this fish is almost unexampled, even in a class remarkable for their omnivorous propensities. Goslings, young ducks, and coots, water-rats, kittens, and the young of its own species, besides every kind of fresh-water fish, have been found in the stomach of the pike. It is said to contend with the otter for its prey, and has been known to pull a mule into the water by the nose. This fish is in season from May to February, and is angled for by trolling with a strong-topped rod. The hooks are generally fastened to a bit of brass wire for a few inches from the shaft, to prevent the line from being snapped. Different methods are used in angling for pike. *Trolling*, in the more limited sense of the word, signifies catching fish with the gorge hook, which is composed of two, or what is called a double eel-hook; *live bait-fishing* is practised with the aid of a floated line; and *snap-fishing* consists in the use of large hooks, so baited as to enable the angler to strike the fish the moment he feels it bite, immediately after which he drags it *nolens volens* ashore.

Trolling for pike may be practised during the winter months, when trout fishing has ceased; and the colder season of the year is in fact more convenient for the sport, owing to the decay or diminution of the weeds which usually surround their favourite haunts. With the exception of chub and dace, which bite pretty freely at the bottom all winter, scarcely any other fish can be relied upon for sport during the more inclement portion of the year. To bait a gorge hook, take a baiting needle, and hook the curved end to the loop of the gimp, to which the hook is tied; see Plate XLI. fig. 20; then introduce the point of the needle into a dead bait's mouth, and bring it out at the middle of the fork of the tail, by which means the piece of lead which covers the shank of the hook, and part of the connecting wire, will lie concealed in the interior of the bait: the shank will be in the inside of its mouth, and the barbs on the outside, turning upwards. See Plate LXI. fig. 24. To keep the bait steady on the hook, fasten the tail part just

tions as the Clyde above the falls, the waters of which have no communication with any lake. This species sometimes attains the weight of 8, 10, or even 12 pounds; but it differs from the Loch Awe trout in being generally, if not exclusively, found in rivers. Those of many of the lesser Highland lakes, such as Loch Ard and Loch Chon, ascend the mountain streams in the autumn to spawn, and in the ordinary practice of angling (with the artificial fly) are rarely caught above the weight of three pounds. In the year 1829 we received some very singular trouts from a small loch called Lochdow, near Pitmain, in Inverness-shire. Their heads were short and round, and their upper jaws were truncated like that of a bull-dog. They do not occur in any of the neighbouring lochs, and have not been observed above the weight of half a pound. Trouts of the ordinary shape likewise occur in Lochdow

Angling.

above the fork to the gimp, with a silk or cotton thread; or a neater method is, to pass the needle and thread through the side of the bait, about half an inch above the tail, so as to encircle the gimp in the interior. The baits used vary in weight from one to four ounces, and the hooks must be proportioned to the size of the fish with which they are baited. The barbs of the hook ought not to project much beyond the sides of the mouth, because, as the pike generally seizes his prey crosswise, and turns it before it is pouched or swallowed, if he feels the points of the hook he may cast it out entirely.

In trolling for pike, it is advised to keep as far from the water as possible, and to commence casting close by the near shore, with the wind blowing from behind. When the water is clear and the weather bright, some prefer to fish against the wind. "After trying closely," says Mr Salter, "make your next throw further in the water, and draw and sink the baited hook, drawing it straight upwards near to the surface of the water, and also to right and left, searching carefully every foot of water; and draw your bait with the stream, because you must know that jack and pike lay in wait for food with their heads and eyes pointing up the stream, to catch what may be coming down; therefore experienced trollers fish a river or stream down, or obliquely across; but the inconsiderate as frequently troll against the stream, which is improper, because they then draw their baited hook behind either jack or pike when they are stationary, instead of bringing it before his eyes and mouth to tempt him. *Note.*—Be particularly careful, in drawing up or taking the baited hook out of the water, not to do it too hastily, because you will find by experience that the jack and pike strike or seize your bait more frequently when you are drawing it upwards than when it is sinking. And also further observe, that when drawing your bait upwards, if you occasionally shake the rod, it will cause the bait to spin and twist about, which is very likely to attract either jack or pike."[1]

These fish are partial to the bends of rivers and the bays of lakes, where the water is shallow, and abounding in weeds, reeds, water lilies, &c. In fishing with the gorge hook, and the angler feels a run, he ought not to strike for several minutes after the fish has become stationary, lest he pull the bait away before it is fairly pouched. If a pike makes a very short run, then remains stationary for about a minute, and again makes one or two short runs, he is probably merely retiring to some quiet haunt before he swallows the bait; but if, after remaining still for three or four minutes, he begins to shake the line and move about, the inference is that he has pouched the bait, and feels some annoyance from the hook within, then such part of the line as has been slackened may be wound up, and the fish struck. It is an unsafe practice to lay down the rod during the interval between a run and the supposed pouching of the bait, because it not unfrequently happens that a heavy fish, when he first feels the hooks in his interior, will make a sudden and most violent rush up the river or along the lake, and the line is either instantly broken, or is carried, together with both the rod and reel, for ever beyond the angler's reach. "When the pike cometh," says Colonel Venables, "you may see the water move, at least you may feel him; then slack your line and give him length enough to run away to his hould, whither he will go directly, and there pouch it, ever beginning (as you may observe) with the head, swallowing that first. Thus let him lye untill you see the line move in the water, and then you may certainly conclude he hath pouched your bait, and rangeth about for more; then with your trowl wind up your line till you think you have it almost streight, then with a smart jerk hook him, and make your pleasure to your content."[2]

The fresher and cleaner the bait is kept, whether for trolling, live-bait, or snap-fishing, the greater is the chance of success.

As pike, notwithstanding their usual voracity, are sometimes, as the anglers phrase it, more on the play than the feed, they will occasionally seize the bait across the body, and, instead of swallowing it, blow it from them repeatedly and then take no further notice of it. The skilful and wily angler must instantly convert his gorge into a snap, and strike him in the lips or jaws when he next attempts such dangerous amusement. The dead snap may be made either with two or four hooks. (See Plate XLI. fig. 21.) Take about twelve inches of stout gimp, make a loop at one end, at the other tie a hook (size No. 2), and about an inch farther up the gimp tie another hook of the same dimensions; then pass the loop of the gimp into the gill of a dead bait-fish, and out at its mouth, and draw the gimp till the hook at the bottom comes just behind the back fin of the bait, and the point and barb are made to pierce slightly through its skin, which keeps the whole steady: now pass the ring of a drop-bead lead over the loop of the gimp, fix the lead inside the bait's mouth, and sew the mouth up. (See Plate XLI. fig. 22.) This will suffice for the snap with a couple of hooks. If the four-hooked snap is desired (and it is very killing), take a piece of stout gimp about four inches long, and making a loop at one end, tie a couple of hooks of the same size, and in the same manner as those before described. After the first two and the lead are in their places, and previous to the sewing up of the mouth, pass the loop of the shorter gimp through the opposite gill, and out at the mouth of the bait; then draw up the hooks till they occupy a position corresponding to those of the other side: next pass the loop of the longer piece of gimp through that of the shorter, and pull all straight: finally, tie the two pieces of gimp together close to the fish's mouth, and sew the latter up.

Some anglers prefer fishing for pike with a floated line and a live bait. When a single hook is used for this purpose, it is baited in one or other of the two following ways: Either pass the point and barb of the hook through the lips of the bait, towards the side of the mouth, or through beneath the base of the anterior portion of the dorsal fin. (See Plate XLI. fig. 25.) When a double hook is used take a baiting needle, hook its curved end into the loop of the gimp, and pass its point beneath the skin of the bait from behind the gills upwards in a sloping direction, bringing it out behind the extremity of the dorsal fin; then draw the gimp till the bend of the hooks are brought to the place where the needle entered, and attach the loop to the trolling line. (See Plate XLI. fig. 23.) Unless a kind of snap-fishing is intended, the hooks for the above purpose should be of such a size as that neither the points nor the barbs project beyond either the shoulder or the belly of the bait.

Snap-fishing is certainly a less scientific method of angling for pike than that with the gorge or live bait; for when the hooks are baited the angler casts in search, draws, raises, and sinks his bait, until he feels a bite. He then strikes with violence, and drags or throws his victim on shore; for there is little fear of his tackle giving way,

---

[1] *The Troller's Guide*, by T. F. Salter, Lond. 1820. In the work above quoted will be found a full account of the necessary implements, and the most approved practice, in this department of the art.

[2] *The Experienced Angler*, p. 36. Third edit. Lond. 1668.

as that used in snap-fishing is of the largest and strongest kind. "This hurried and unsportsman-like way of taking fish," it is observed in the *Troller's Guide*, "can only please those who value the game more than the sport afforded by killing a jack or pike with tackle which gives the fish a chance of escaping, and excites the angler's skill and patience, mixed with a certain pleasing anxiety, and the reward of his hopes. Neither has the snap-fisher so good a chance of success, unless he angles in a pond or piece of water where the jack or pike are very numerous or half starved, and will hazard their lives for almost any thing that comes in their way. But in rivers where they are well fed, worth killing, and rather scarce, the coarse snap-tackle, large hooks, &c. generally alarm them. On the whole, I think it is two to one against the snap in most rivers; and if there are many weeds in the water, the large hooks of the snap, by standing rank, are continually getting foul, damaging the bait, and causing much trouble and loss of time."

Pike sometimes rise at an artificial fly, especially in dark, windy days. The fly ought to be dressed upon a double hook, and composed of very gaudy materials. The head is formed of a little fur, some gold twist, and (if the angler's taste inclines that way, for it is probably a matter of indifference to the fish) two small black or blue beads for eyes. The body is framed rough, full, and round, the wings not parted, but made to stand upright on the back, with some small feathers continued down the back to the end of the tail, so that when finished they may exceed the length of the hook. The whole should be about the bulk of a wren. The largest pike ever killed in Britain was taken with a peacock-feather fly in Loch Ken, near New Galloway. It weighed 72 pounds.[1]

During clear and calm weather in summer and autumn, pike take most freely about three in the afternoon: in winter they may be angled for with equal chances of success during the whole day: early in the morning and late in the evening are the periods best adapted for the spring.

The Carp. (*Cyprinus Carpio.*)

This fish, like the preceding, is asserted to have been introduced into England by Leonard Mascal, a gentleman of Sussex, early in the 16th century; and in good company, if there is truth in the old distich,

> Turkies, carps, hops, pickerell, and beer,
> Came into England all in one year.

The carp is, however, mentioned as a *dayntous fysshe*, though scarce, by Juliana Berners, in the year 1496. It attains to a prodigious size in the waters of the south of Europe, and in the Lake of Como is said sometimes to weigh 200 pounds. It breeds more freely in ponds than in rivers, although those of the latter are more esteemed. Angling for carp requires, according to Walton, "a very large measure of patience." The haunts of this fish in the winter months are the broadest and least disturbed parts of rivers, where the bottom is soft and muddy; but in summer it usually lies in deep holes, near some *scour*, under roots of trees, and beneath hollow banks, or in the neighbourhood of beds of aquatic weeds. In ponds they thrive best in a rich marl or clayey soil, where they have the benefit of shade from an overhanging grove of trees.

Small carp bite eagerly, but the larger and more experienced fish are deceived with difficulty. The rod should be of good length, the line strong, furnished with a quill float, and ending in a few lengths of the best silk-worm gut. The hook is proportioned to the size of the bait, and a single shot is fixed about 12 inches above it. "Three rods," says Daniel, "may be employed; one with the bait at mid-water, another a foot or less from the bottom, and the third to lie upon it when the line and lead are not discovered, as in the two former; the places intended to be fished in should, the night before, be ground-baited with grains, blood, and broken worms, incorporated together with clay, the hook baits should be red worms taken out of tan, flag or marsh-worms, green peas so boiled as to soften, but not to break the skin, and throwing some in now and then. When this bait is used (which should be with one on the hook to swim a foot from the ground), in case of a bite, strike immediately; a large carp, upon taking the bait, directly steers for the opposite side of the river or pond."[2] During hot weather, when these fish are about to spawn, and whilst lying among the weeds near the surface, they may be angled for with a fine line, without either sink or float. The hook may be baited with a red worm, a pair of gentles, a caterpillar, or a cad bait, and thrown lightly as in fly-fishing, and then drawn towards the angler. If it can be made to fall first upon the leaf of some water plant, and then dropped upon the surface, the chance of success will be increased. The best months are May, June, and July, and the most advisable times of the day are from sunrise to eight in the morning, and from sunset during the continuance of twilight, and onwards through the night. It is the opinion of many, though we cannot trace the origin of the idea, no doubt an erroneous one, that the 10th of April is a fatal day for carp.

The Bream. (*Cyprinus Brama.*)

This fish breeds both in deep, slow-running rivers, and in ponds. It prefers the latter. The most enticing bait is a well-conditioned earthworm, although the angler also uses paste made of bread and honey, wasp grubs, grass-hoppers, &c. Boiled wheat serves well for ground-baiting the spot on the preceding nights, and some fasten a number of worms to a piece of turf, and sink it to the bottom. When the ground has been thus prepared, and the tackle put in order, the angler should commence his labours by three or four in the morning. Let him approach the place with caution, so as not to be perceived by the fish, and cast his hook neatly baited with a live and moving worm, in such manner that the lead may lie about the centre of the prepared ground. The bream is a strong fish, and runs smartly when first struck; but after a few turns he falls over on his side, and allows the angler to land him without much trouble. He is by no means so lively as the carp. The best hours for bream are from four till eight in the morning, and from four in the afternoon till eight in the evening. In the river Trent, near Newark, there are two kinds of bream. The common species is that called the carp bream, from its yellow colour; and it sometimes attains the weight of eight pounds. The other species or variety, regarded by Mr Revett Shepherd as a nondescript, never exceeds a pound in weight. It is of a silvery hue, and is known by the name of white bream.[3] The bream, though rare in Scotland, occurs in Loch Maben.

The Tench. (*Cyprinus Tinca.*)

This species is a lover of still waters, and his haunts in rivers are among weeds, or pools well screened by bushes. Tench are found spawning from June till September, and they are in the best condition from the latter month till the end of May. The tackle should be strong, with a swan or goose-quill float for ponds, and a piece of cork for rivers. The hook (in size from No. 4 to 6) should

[1] Daniel's *Rural Sports*, vol. ii. p. 275.

[2] *Ibid.* p. 257.

[3] *Linn. Trans.* vol. xiv. p. 587.

be whipt to sound silk-worm gut, with two or three shot fixed to it at the distance of a foot. The bait should float about a couple of feet from the surface, and should be drawn occasionally gently upwards, and allowed slowly to sink again. Small marsh worms, middle-sized lobs, or the red species found in rotten tan, are to be recommended. " He will bite," says Walton, " at a paste made of brown bread and honey, or at a marsh-worm, or a lob-worm: he inclines very much to any paste with which tan is mixed, and he will bite also at a smaller worm with his head nipped off, and a sod-worm put on the hook before that worm; and I doubt not but that he will also in the three hot months, for in the nine colder he stirs not much, bite at a flag-worm, or at a green gentle: but can positively say no more of the tench, he being a fish that I have not often angled for; but I wish my honest scholar may, and be ever fortunate when he fishes."

The Barbel. (*Cyprinus Barbus.*)

In a culinary point of view this is one of the worst of the fresh-water fishes. It is gregarious, and roots among the soft banks with its nose, like a sow. The angling season commences in May, and continues till September. The most approved hours are from daylight till ten in the morning, and from four in the afternoon till about sunset. The line should be strong and rather heavily leaded, so that the bait may float about half an inch from the ground. Considerable caution is required in playing this fish, as he is apt to run off when struck, with great violence, towards some stronghold, and in so doing sometimes breaks both rod and line. He is rather nice in his baits, which must be kept clean and sweet, and untainted by musty moss. " One caution," says Mr Daniel, " in angling for barbel, will bear repetition: never throw in the bait farther than enabled by a gentle cast of the rod, letting the plumb fall into the water with the least possible noise. It is an error to think that large fish are in the middle of the river: experience teaches the fallacy of this opinion: they naturally seek their food near the banks, and agitating the waters by an injudicious management of the plumb will certainly drive them away. It is incredible the quantities of barbel sometimes caught by this method. Persons of great veracity have asserted that upwards of one hundredweight have been taken in one morning."

The Chub. (*Cyprinus Cephalus.*)

The rivers of England are stored with a much finer variety of fresh-water fish than those of Scotland. The chub occurs in the Annan. It is however a fish but lightly esteemed, either for sport or the table. He is a dull fish on the hook, bites eagerly, and is soon tired. Caution is requisite on the part of the angler, as the chub is naturally fearful, and sinks towards the bottom of the stream on the slightest alarm. The baits used are maggots, beetles, grasshoppers, salmon-roe, &c. Black and dun flies gaudily dressed, and ribbed with gold or silver twist, are well adapted to take them in streams. They likewise rise at the red-spinner. But perhaps the best way to secure this fish is by *dibbing* with a grasshopper. As chub are often seen in some favourite haunt lying near the surface of the pool, the angler, concealing himself as much as possible, ought to move his rod cautiously over the spot, and drop his bait gently upon the water, a few inches in advance of the fish's head. The landing net is particularly necessary in angling for chub, as the best spots are generally encumbered by trees or bushes, which prevent the fish from being drawn to hand, or pulled ashore.

The Dace. (*Cyprinus Leuciscus.*)

This fish is of gregarious habits, and haunts the deeper waters near the piles of bridges, shady pools, and beneath the masses of collected foam caused by eddies. In the warmer months of the year they also congregate in the shallows. They rise at a variety of flies, and are likewise angled for with red worms, brandlings, &c. Above Richmond, as soon as the weeds begin to rot, a grasshopper used as an artificial fly is found very successful in hot weather among the shallows. This mode can only be practised in a boat, with a heavy stone to serve as an anchor, fastened to a few yards of rope. The boat drifts gently down the stream, and the stone is dropped whenever the angler considers himself in the neighbourhood of a likely place. Standing in the stern, he first throws directly down the stream, and then to the right and left; and after trying for about a quarter of an hour in one spot, he again weighs anchor, and proceeds to another station.

The Roach. (*Cyprinus Rutilus.*)

The carp has been named the " water-fox" on account of his subtlety, and the roach the " water-sheep," by reason of his silliness. This fish makes good soup, though very bony, and otherwise not much esteemed. The season for roach fishing in the Thames, where it attains to a larger size than elsewhere, commences about the end of August. " Next let me tell you," says Walton, " you shall fish for this roach in winter with paste or gentles, in April with worms or caddis, in the very hot months with little white snails, or with flies under water; for he seldom takes them at the top, though the dace will. In many of the hot months roaches may be also caught thus:—Take a May-fly or ant-fly; sink him with a little lead to the bottom, near the piles or posts of a bridge, or near to any posts of a wear—I mean any deep place where roaches lie quietly—and then pull your fly up very leisurely, and usually a roach will follow your bait to the very top of the water, and gaze on it there, and run at it, and take it, lest the fly should fly away from him."[1] Vast shoals of this species ascend the streams in the parish of Killearn, from Loch Lomond, and are caught by nets in thousands. Their emigration from the loch, however, continues only for the space of three or four days towards the end of May.[2]

The Bleak. (*Cyprinus Alburnus.*)

This small and active fish may be angled for with what is called a *pater noster* line, which consists of half a dozen fine hooks fastened about 6 or 8 inches from each other. These may be baited with gentles, or more variously, to increase the temptation, with a gentle, a small red worm, a fly, &c. and thus several fish may be hooked at the same time. In angling for bleak the tackle must be very fine. In fresh streams they rise well at the black gnat, or any other small sad-coloured fly.

The Gudgeon. (*Cyprinus Gobio.*)

Gudgeons are angled for near the ground with a small red worm. They frequent the shallows during the hot months, and retire before winter to the stiller and deeper waters. As an article of food they are highly esteemed.

The Minnow. (*Cyprinus Phoxinus.*)

This is the fish by means of which most youthful anglers commence their experience of the art. " He is a sharp biter," says Walton, " at a small worm, and in hot

[1] *Complete Angler*, p. 218.

[2] *Statistical Account of Scotland*, vol. xvi. p. 100.

weather makes excellent sport for young anglers, or boys, or women that love that recreation; and in the spring they make of them excellent minnow-tansies; for being washed well in salt, and their heads and tails cut off, and their guts taken out, and not washed after, they prove excellent for that use; that is, being fried with yolks of eggs, the flower of cowslips and of primroses, and a little tansie. Thus used, they make a dainty dish of meat."

The Loach. (*Cobitis Barbatula.*)

The loach is entirely a ground fish, living in clear and gravelly streams. It is an excellent bait for eels, and is also a nutritious food for man, though of a slimy and somewhat forbidding aspect.

The Eel. (*Anguilla Vulgaris.*)

This well-known and snake-like species has its favourite haunts in the muddy bottom of the bays of lakes, among weeds, under large stones, and in the clefts of the banks of rivers. The habits of the eel are nocturnal, and the largest and finest are usually caught with night-lines. They are troublesome fish, from their great tenacity of life, and the tortuous motions by which, in their endeavours to disengage themselves, they entangle or destroy the angler's tackle. They afford little amusement to those accustomed to the more elegant branches of the art.

The isle of Ely, according to some authorities, was so called in consequence of its being the place from whence the kings of England were anciently supplied with eels. Indeed Cambridgeshire is still famous for this fish.[1]

The Perch. (*Perca Fluviatilis.*)

This gregarious fish is angled for with a worm or minnow. It is a bold biter during the warm months of the year, though very abstemious in the winter season. When a shoal is met with, great sport is frequently obtained. A small cork float is used, and the bait is hung at various depths, according to circumstances, a knowledge of which can only be obtained by practice. In angling near the bottom, the bait should be frequently raised nearly to the surface, and then allowed gently to sink again. When the weather is cool and cloudy, with a ruffling breeze from the south, perch will bite during the whole day. The best hours towards the end of spring are from seven to eleven in the morning, and from two to six in the afternoon. In warm and bright summer weather, excellent times are from sunrise till six or seven in the morning, and from six in the evening till sunset.

The first printed work on angling in the English language is by Dame Juliana Barnes or Berners (*The Treatyse of Fysshinge with an Angle*), and forms part of the *Book of St Alban's, emprented at Westmestre by Wynken de Worde*, in 1496. Of this book there are various old editions, and it has, we believe, been twice reprinted in modern times. It is less useful to the angler than curious in the eyes of the bibliographer. Hawking, Hunting, Fouling, and Fishing, with the true measures of Blowing, &c. now newly collected by W. G. Faukener. 4to, Lond. 1596. A Book of Fishing with Hooke and Line, and of all other Instruments thereunto belonginge, made by L. M. 4to, Lond. 1590. This work contains remarks on the preservation of fish in pools, and some improvements on the directions of the "religious sportswoman" Juliana Barnes. L. M. signifies Leonard Mascall. A Neu Book of good Husbandry, very pleasaunt, and of great profite, both for gentlemen and yeomen; conteining the Order and Maner of Making of Fish-pondes, with the Breeding, Preseruing, and Multiplyinge of the Carpe, Tench, Pike, and Troute, and diverse kindes of other Fresh Fish. Written in Latine by Janus Dubrauius, and translated into English at the speciale request of George Churchey, Fellow of Lion's Inne, the 9th Februarie 1599. 4to, Lond. 1599. Certain Experiments concerning Fish and Fruit, practised by John Taverner, Gentleman, and by him published for the benefit of others. 4to, Lond. 1600. The Secrets of Angling; teaching the Choicest Tooles, Baytes, and Seasons for the taking of any Fish in Pond or River: practised and familiarly opened in Three Bookes. By J. D., Esquire. 8vo, Lond. 1613. The author of this work is named in the third edition of Walton's Angler as one Jo. Davors; but, from an entry in the books of Stationers Hall, as given in the second volume of "British Bibliography," p. 355, he is mentioned as John Dennys, Esquire. Large extracts from this work are given by Sir Egerton Bridges, in the last volume of his *Censura Literaria.* The poetry, of which several passages are quoted by Walton, is remarkable for its beauty. As the volume is rare, we shall here present the reader with a few stanzas.

> You nymphs that in the springs and waters sweet
> Your dwelling have, of every hill and dale,
> And oft amid the meadows green do meet
> To sport and play, and hear the nightingale,
> And in the rivers fresh do wash your feet,
> While Progne's sister tells her wofull tale;
> Such ayd and power unto my verses lend
> As may suffice this little work to end.
>
> And thou, sweet Boyd, that with thy wat'ry sway
> Dost wash the cliffes of Deignton and of Week,
> And through their rocks with crooked winding way
> Thy mother Avon runnest soft to seek;
> In whose fair streams the speckled trout doth play,
> The roach, the dace, the gudgin, and the bleike;
> Teach me the skill, with slender line and hook,
> To take each fish of river, pond, and brook.

In comparing the amusement of angling with the excitement to be derived from gaming and other pleasures, he adds—

> O let me rather on the pleasant brinke
> Of Tyne and Trent possess some dwelling place,
> Where I may see my quill and corke down sinke,
> With eager bite of barbel, bleike, or dace;
> And on the world and his Creatour thinke,
> While they proud Thais painted sheet embrace;
> And with the fume of strong tobacco smoke
> And quaffing round are ready for to choke.
>
> Let them that list these pastimes then pursue,
> And on their pleasing fancies feed their fill;
> So I the fields and meadows green may view,
> And by the rivers fresh may walke at wille,
> Among the dazies and the violets blue,
> Red hyacinth and yellow daffodil,
> Purple narcissus like the morning rayes,
> Pale ganderglas, and azore culverkayes.
>
> I count it better pleasure to behold
> The goodly compasse of the lofty skie;
> And in the midst thereof, like burning gold,
> The flaming chariot of the world's great eye;

---

[1] "Here I hope I shall not tresspass upon gravity, in mentioning a passage observed by the reverend professor of Oxford, Doctor Prideaux, referring the reader to him for the author's attesting the same. When the priests in this part of the country would still retain their wives, in despight of whatever the pope or monks would doe to the contrary, their wives and children were miraculously turned all into eels (surely the great into *Congers*, the less into Greggs), whence it had the name of Eely. I understand him, a Lie of Eels." (Fuller's *Worthies. Cambridgeshire.*)

The wat'ry clouds that in the ayre uprol'd
With sundry kinds of painted colours flie;
And faire Aurora lifting up her head,
All blushing rise from old Tithonus bed.

The hills and mountains raised from the plains,
The plains extended levell with the ground,
The ground divided into sundry vains,
The vains enclos'd with running rivers round,
The rivers making way thro' nature's chains,
With headlong course into the sea profound;
The surging sea beneath the vallies low,
The vallies sweet, and lakes that lovely flow.

Then follow the two stanzas quoted at the beginning of this article. Our next work on angling is The Pleasures of Princes, or Good Men's Recreations; containing a Discourse of the General Art of Fishing with the Angle, or otherwise, and of all the hidden secrets belonging thereunto; together with the Choyce, Ordering, Breeding, and Dyetting of the Fighting Cocke; being a worke never in that nature handled by any former author. Lond. 1614, 4to. This work forms part of the second book of the English Husbandman, by G. M. (Gervais Markham.) A Briefe Treatise of Fishing; with the Art of Angling. Lond. 1614, 4to. This work is little else than a reprint from a portion of the Book of St Alban's, and forms part of the Jewell for Gentrie, by T. S. Cheap and Good Husbandry, by Gervais Markham. 4to, Lond. 1616. This work contains a chapter on Fish and Fish-Ponds. Country Contentments; or the Husbandman's Recreations, by J. M. In the fifth and sixth editions of this volume (4to, Lond. 1633 and 1639), will be found, the Whole Art of Angling, as it was written in a small treatise in rime, and now, for the better understanding of the reader, put into prose, and adorned and enlarged. This work is a prose version, with additions, of Davors' Secrets of Angling. The Country Gentleman's Companion, 2 vols. 12mo, Lond. 1753, is a reprint, without acknowledgement, of Markham's work. The Art of Angling; wherein are discovered many rare secrets very necessary to be known by all that delight in that recreation, written by Thomas Barker, an antient practitioner in the said art. 12mo, Lond. 1651. In an epistle to the reader, prefixed to the first edition, and in the dedication of the two last to Edward Lord Montague, Barker speaks of himself as having practised angling for more than half a century. He also says he was born and educated at Bracemeall, in the liberty of Salop, being a freeman and burgesse of the same city; adding, "if any noble or gentle angler, of whatever degree soever he be, have a mind to discourse of any of these wayes and experiments, I live in Henry the 7th's Gifts, the next doore to the Gatehouse, in Westm. My name is Barker, where I shall be ready, as long as please God, to satisfye them, and maintain my art during life, which is not like to be long." See British Bibliography, by Sir Eg. Bridges and Joseph Haselwood, vol. ii. p. 356. The Compleat Angler, or the Contemplative Man's Recreation; being a discourse of Fish and Fishing, not unworthy the perusal of most anglers. 12mo, Lond. 1653. This is the first edition of Izaak Walton's celebrated work. It went through five editions during the author's lifetime; and in the course of its republication was enlarged and improved. The fifth edition forms the first part of the Universal Angler, by Walton, Cotton, and Venables, 12mo, Lond. 1676; and is accompanied by a *second part* (written by Cotton), which treats more fully of fly-fishing. The sixth and seventh editions were published in 1750 and 1759, by Moses Browne, author of the Piscatory Eclogues and other works. The eighth edition was published by Sir John Hawkins in 1760, and has been succeeded by many others since that period, of which the most recent and most beautifully adorned is that by John Major, with an introductory essay and illustrative notes. 8vo, Lond. 1823. The third edition of the Compleat Gentleman, by Henry Peacham, 4to, Lond. 1661, contains a chapter concerning Fishing. The Experienced Angler, or Angling Improved; being a general discourse of Angling. 8vo, Lond. 1662. This work, of which there are several editions, is by Colonel Robert Venables. Its fourth edition forms the third part of the Universal Angler. Angling Improved to Spiritual Uses, forms part of an octavo volume entitled Occasional Reflections upon several Subjects, by the Hon. Robert Boyle. 8vo, Lond. 1665. In a volume called The Epitome of the Art of Husbandry, by J. B. Gent. 12mo, Lond. 1669, are brief experimental directions for the right use of the angle. The author's name was Blagrave. The Angler's Delight; containing the whole Art of Neat and Clean Angling; wherein is taught the readiest way to take all sorts of Fish, from the Pike to the Minnow, together with their proper baits, haunts, and time of fishing for them, whether in mere, pond, or river. As also the method of fishing in Hackney River, and the names of all the best stands there; with the manner of making all sorts of good tackle fit for any water whatsoever. The like never before in print. By William Gilbert, Gent. 12mo, Lond. 1676. The Compleat Troller, or the Art of Trolling, by Robert Nobbes. 8vo, Lond. 1682. There are several editions of this work, of which the third and fourth are appended to the Angler's Pocket-Book. Gentleman's Recreations; treating of the Art of Horsemanship, Hunting, Fowling, Fishing, and Agriculture. Fol. Lond. 1686. The Gentleman's Recreation, in four parts, viz. Hunting, Hawking, Fowling, Fishing. 8vo, Lond. 1674. (By Nicholas Cox.) The Angler's Vade Mecum, or a compendious yet full Discourse of Angling. By T. Cheetham. 8vo, Lond. 1681. Northern Memoirs, calculated for the meridian of Scotland; wherein most or all of the Cities, Citadels, Seaports, Castles, Forts, Fortresses, Rivers, and Rivulets, are compendiously described; to which is added, the Contemplative and Practical Angler, by way of diversion; with a Narrative of that dextrous and mysterious Art experimented in England, and perfected in more remote and solitary parts of Scotland; by way of Dialogue: writ in the year 1658, but not till now made publick. By Richard Franck, Philanthropus. 8vo, Lond. 1694. Of this curious volume a reprint was published of late years. The Gentleman Fisher; or the Whole Art of Angling. 8vo, Lond., second edition, 1727. The True Art of Angling, by J. S. 24to, Lond. 1696. The Compleat Fisher, or the True Art of Angling, by J. S., third edition, 1704. The preceding work, revised and corrected by W. Wright and other experienced anglers, was republished in 1740. The Compleat Fisherman; being a large and particular account of all the several ways of Fishing now practised in Europe; by James Saunders, Esq. of Newton-Awbery, upon Trent. 12mo, Lond. 1724. The Genteel Recreation, or the Pleasure of Angling; a Poem: with a dialogue between Piscator and Corydon. By John Whitney, a lover of the Angle. 8vo, Lond. 1700. The School of Recreation, or a Guide to the most ingenious Exercises; by R. H. 8vo, Lond. 1701. The Secrets of Angling, by C. G. 12mo, Lond. 1705. The Angler's Sure Guide, or Angling Improved and Methodically Digested, by R. H. Esq. 8vo, Lond. 1706. The Innocent Epicure, or the Art of Angling; a Poem. 8vo, Lond. 1697. The whole Art of Fishing, being a Collection and Improvement of all that has been written on this subject; with many new experiments. 12mo, Lond. 1714. The second edition of this work is entitled The Gentleman Fisher, or the whole Art of Angling. 8vo, Lond. 1727. A Discourse of Fish and Fish-Ponds, by a Person of Honour. 8vo. London.

The author of this work was the Hon. Roger North. A subsequent edition (of which there were more than one) bears the date of 1713. It was also published as an appendage to the Gentleman Farmer. 8vo, Lond. 1726. The Country Gentleman's Vade Mecum, by G. Jacob, Gent. 8vo, Lond. 1717; and the Compleat Sportsman, by the same author (1718), of which the 3d part relates to Fish and Fishing. England's Interest, or the Gentleman and Farmer's Friend, by Sir John Moore. 8vo, Lond. 1721. The Gentleman Angler, Lond. 1726. Piscatory Eclogues (by Moses Browne). 8vo, Lond. 1729. Of this work there are several editions. Sportsman's Dictionary, or the Gentleman's Companion in all Rural Recreations. 2 vols. 8vo, 1735. The British Angler, or a Pocket Companion for Gentlemen Fishers, by John Williamson, Gent. 8vo, Lond. 1740. The Art of Angling, Rock and Sea Fishing, with a Natural History of River, Pond, and Sea Fish, by R. Brookes. 8vo, Lond. 1740. Of this treatise there have been various reprints, at different periods, up to the year 1807. Angling, a Poem. 12mo, Lond. 1741, 2d edit. The Art of Angling improved in all its Parts, especially Fly-fishing, by Richard Bowlker. 12mo, Worcester. Published some time preceding the year 1759. There is a recent edition (1806) by Charles Bowlker, Ludlow. The Angler's Magazine, or Necessary and Delightful Store House; wherein every thing proper to be known relating to his art is digested in such a method as to assist his knowledge and practice upon bare inspection; being the completest manual ever published upon the subject, largely treating of all things relating to Fish and Fishing, and whereby the angler may acquire his experience without the help of a master. By a Lover of that innocent and healthful diversion. 12mo, Lond. 1754. The Angler's Eight Dialogues, in Verse. 8vo, Lond. 1758. The Art of Angling, eight Dialogues, in Verse. 8vo. The Universal Angler, or that art Improved in all its Parts, especially in Fly-fishing. 8vo, Lond. 1766. The Complete Sportsman, or Country Gentleman's Recreation, by Thomas Fairfax. 8vo, London. The Complete Fisherman, or Universal Angler. 8vo, Lond. (2d edit.) Lond. 1778. The Angler's Complete Assistant, being an Epitome of the whole Art of Angling. 4th edit. 4to, London. The True Art of Angling. 12mo, Lond. 1770. Translation of a Letter from the Hanover Magazine, No. 23, March 21, 1763; giving an account of a method to breed fish to advantage. 8vo, Lond. 1778. The Angler's Museum, or the whole Art of Float and Fly Fishing, by Thomas Shirley. 12mo, Lond. 1784. The Fisherman, or Art of Angling made Easy, by Guiniad Charfey, Esq. 8vo, London. The North Country Angler, or the Art of Angling as practised in the Northern Counties of England. 8vo, Lond. 1786. A Concise Treatise on the Art of Angling, by Thomas Best, Gent. 8vo, Lond. 1787. Of this work there have been published many editions, of which the 9th is dated 1810. An Essay on the Right of Angling in the River Thames, and in all the other public Navigable Rivers. 8vo, Reading. A Letter to a Proprietor of a Fishery in the River Thames; in which an attempt is made to show in whom the right of Fishing in public streams now resides. 2d edit. 8vo, Reading, 1787. The Natural History of Fishes and Serpents, by R. Brookes; to which is added, an Appendix, containing the whole Art of Float and Fly Fishing. 8vo, Lond. 1790. The Young Angler's Pocket Companion, by Ralph Cole, Gent. 12mo, Lond. 1795. The Modern Angler, being a practical Treatise on the Art of Fishing, &c., in a series of Letters to a Friend; by Robert Salter, Esq. 12mo, London. Angling in all its branches reduced to a complete Science, in three parts, by Samuel Taylor, Gent. 8vo, London, 1800. Practical Observations on Angling in the River Trent. 8vo, Newark, 1801. Every Man his own Fisherman, by Thomas Smith. 24to, London. The Driffield Angler, in two parts, by Alexander Mackintosh of Great Driffield, Yorkshire. 8vo, Gainsborough. The Angler's Pocket Book; to which is prefixed, Nobbes' celebrated Treatise on the Art of Trolling. 8vo, Norw. The New and Complete Angler, or Universal Fisherman, by Richard Pollard, Esq. of Clapton, Middlesex. 8vo, Lond. 1802. Rural Sports, by W. B. Daniel. 4to, Lond. 1802. Part of vol. ii. relates to fly-fishing, and the other kinds of angling. The Kentish Angler, or the Young Fisherman's Instructor; showing the nature and properties of Fish which are angled for in Kent. 12mo, Canterb. 1804. The Complete Angler's Vade Mecum, being a perfect Code of Instruction on the above pleasing Science, &c., by Captain T. Williamson. 8vo, London, 1808. The Angler's Manual, or concise Lessons of Experience, which the proficient in the delightful recreation of Angling will not despise, and the Learners will find the advantage of practising; containing useful Instructions on every approved method of Angling, and particularly on the management of the Hand and Rod in each method. 4to, Liverpool, 1808. The Fisher's Boy, a Poem, by W. H. Ireland. 8vo, 1808. The Angler's Manual, or concise Lessons of Experience, &c. 8vo, 1809. Practical Observations on Angling in the River Trent. 12mo, 1812. Daniel's Rural Sports. Royal 8vo, 1812. Howitt's Foreign Field Sports, Fisheries, &c. 4to, 1814. The Secrets of Angling, by J. D. (Davors); augmented by W. Lawson. 8vo, 1814. The Angler's Guide, by T. F. Salter. 8vo, 1815. Art of Angling, by Charles Bowlker. 12mo, 1815. The Fly-Fisher's Guide, by G. C. Bainbridge. 8vo, 1816. W. H. Scot's British Field Sports. Royal 8vo, 1818. The Angler's Vade Mecum, by W. Carroll. 12mo, 1818. Sportsman's Repository, by J. Scott, 1820. The Troller's Guide, a new and complete Practical Treatise on the Art of Trolling for Jack and Pike; to which is added, the Best Method of Baiting and Laying Lines for large Eels. By T. F. Salter, author of the Angler's Guide. Small 8vo, Lond. 1820. Instructions to Young Sportsmen, by Lieutenant-Colonel Hawker. Royal 8vo, 1824. Salmonia, or Days of Fly-Fishing. By an Angler (the late Sir Humphry Davy). 12mo, Lond. 1828. There is a recent edition (1852), with Notes, by John Davy, M.D., F.R.S., &c. Angler's Souvenir, by P. Fisher. 12mo. The Art of Angling, by Thomas Barker, 12mo. Angling Excursions, by Geoffry Green-drake. 12mo. Letters on Angling, Shooting, &c., by Robert Lascelles. 8vo. Practical Fly-Fishing, with remarks on Fly Rods. 12mo. The British Angler's Manual, by T. C. Hofland. 8vo, Lond. 1830; (revised by Jesse. 8vo, Lond. 1848.) Alphabet of Scientific Angling, by James Rennie. 12mo, Lond. 1833. Trout and Salmon Fishing in Wales, by G. A. Hansard. 12mo, Lond. 1834. Scenes and Recollections of Fly-Fishing, by Stephen Oliver. 12mo, Lond. 1834. Angler in Wales, by Captain Medwin. 2 vols. 8vo, Lond. 1834. Angler in Ireland, by Belton. 2 vols. post 8vo, Lond. 1834. The Art of Angling as practised in Scotland, by Thomas Tod Stoddart. 12mo, 1835. Piscatorial Reminiscences and Gleanings, by an old Angler. 12mo, Lond. 1835. The Angler's Manual, or Fly-Fisher's Oracle, by John Turton. 12mo, Lond. 1836. Angler's Rambles, by Edward Jesse. Post 8vo, Lond. 1836. Notes on Nets, &c., by Charles Bathurst. 12mo, Lond. 1837. Treatise on the Art of Fly-Fishing, Trolling, &c., by William Shipley. 12mo, Lond. 1838. Maxims and Hints on Angling, by Richard Penn. 12mo, Lond. 1839. Northern Angler: Fly-Fisher's Companion, by John Kirkbride. 12mo, Lond. 1840. Vade Mecum of Fly-Fishing for Trout, by G. P. Pulman. 12mo, Lond. 1840. 3d edit. 1851. The Moor and the Loch, by John Colquhoun. 8vo, Edinburgh, 1840.

Anglo-Calvinists.

Two Summers in Norway, by the author of *Angler in Ireland.* 2 vols. post 8vo, Lond. 1840. Treatise on Salmon and Trout Angling, by J. D. Dougall. 12mo, Lond. 1841. 22. Dead-snap with two hooks baited.
23. Live bait double hook, baited.
24. Gorge-hook, baited.
25. Live bait single hook, baited according to two different methods.

ANGLO-CALVINISTS, a name given by some writers to the members of the Church of England, as agreeing with the other Calvinists in most points except church government.

Anglo-Saxon ‖ Angola.

Anglo-Saxon, an appellation given to the language spoken by the English Saxons, in contradistinction to the true Saxon, as well as to the modern English.

ANGLUS, Thomas. See White, Thomas.

ANGOLA, or Dongo, a territory on the western coast of Africa, between 8° and 10° south latitude. It has Congo on the north; the South Atlantic Ocean on the west; Benguela on the south; and the African States of the interior on the east. It extends about 350 miles from east to west, and between 50 and 60 miles from north to south.

Angola is very mountainous, being destitute of plains except on the sea-shore, and some small plateaux on the sides or in the gorges of the mountains. It is well watered, and, with the exception of the sandy plains on the coast, is very fertile. Its principal rivers are the Coanza, which forms its boundary on the south; the Danda, which bounds it on the north; and the Benga. Here, as in all well-watered tropical countries, vegetation is most luxuriant: palms, the citron, orange, lemon, banana, cocoa, tamarind, mangrove, sugar-cane, vine, and indeed every species of tropical vegetation, is found in great abundance. Nor is the animal kingdom less prolific: all the animals common to inter-tropical Africa are found here, with some peculiar to this part of the country. The sheep, cow, and horse, have been imported from Europe. Its birds are very numerous, and among its reptiles are many of the most venomous. Of its mineral productions, lead, sulphur, petroleum and iron, are plentiful; gold and silver are found in the mountains, and copper is said to exist in the interior. The heat is moderate, and the climate mild and salubrious. Its population is estimated at between two and three millions.

The habitations of the natives are formed merely of straw, or rather of dried leafy plants, cemented by a framework of wooden stakes. Containing no aperture for the admission of light, they form not so properly houses, as dark dens for sleeping in, while the tenants spend the day and receive company in an open space in front, covered with a slight roof. The abodes of the grandees are in no respect superior, except that they consist of a number of these hovels grouped together, and inclosed by a hedge or earthen wall. A village or town consists merely of a cluster of these inclosures, separated by narrow and winding footpaths, and leaving extensive open spaces, which serve for markets or for scenes of recreation. A town in this country at a little distance resembles a wood, from the multitude of trees with which it is filled; but on a near approach its nature is soon detected by the fetid odour exhaling from its precincts.

Like other unenlightened tribes, the natives are deeply addicted to superstition; and it is remarked as a singular circumstance, that their idols do not present the negro visage, but one more nearly approaching to the European. From the slight description that is given, we should suspect the face to be Copt; nor does it seem improbable that the superstitions of Egypt may have found their way throughout the continent. The priests pretend to bestow rain, favourable winds, and various other blessings, upon those who have propitiated them by liberal gifts. Much use is made in criminal cases, of what our ancestors called "the judgments of God." The accused is made to swallow poison, to plunge into water, or to take in his hand burning coals, and, unless he escapes unhurt from these trials, is at once pronounced guilty. It seems reasonably concluded, that the priests who administer these tests contrive to secure immunity to their favourites, or to those who bestow upon them liberal donations.

Vessels destined for the coast of Angola, after reaching Cape Verde, have two routes by which they may proceed.

They may take the *short* route by steering directly along the African coast, through the Gulf of Benin. If favoured by winds and currents, they may make this voyage very speedily; but in the event of these circumstances proving adverse, they are liable to great detention; and the navigation has even occupied eleven months. The other, called the *long* route, is performed by proceeding due south, and even south-west, till they pass the 20th degree of latitude, when a favourable wind and tide carries them directly eastward to the African coast. This route necessarily occupies a considerable time; but is liable to no vicissitude, and the period may be calculated almost to a day.

Angola was discovered in 1484 by Diego Cam, a Portuguese, and soon afterwards several settlements were established there by that government. When Portugal had possession of Brazil, an active slave-trade was carried on with this country; but at present the Portuguese derive little or no benefit from the possession of Angola. They have a governor at the chief town, St Paul de Loando, and possess a few decayed forts in the interior, but have little authority in the country. The principal exports are ivory and gum. (See Bowdich, *Account of the Discoveries of the Portuguese in Angola, &c.*, 1824. G. Tams, *Die Portugiesischen Besitzungen in Süd-West-Afrika.* Hamburg, 1845.)

ANGON, in the *Ancient Military Art*, a kind of javelin used by the French. They darted it at a considerable distance. The iron head of this weapon resembled a fleur-de-luce. It is the opinion of some writers that the arms of France are not fleurs-de-luce, but the iron point of the angon or javelin of the ancient French.

ANGORA, or Enguri (the Ancyra of the ancients), a town of Natolia, capital of a sandjak of the same name. It stands on an eminence 140 miles north of Konieh, in Lat. 40. 2. N.; Long. 33. 5. E. Its population is variously estimated at from 20,000 to 60,000, including Mahometans, Armenians, Greeks, and Jews. There are still to be seen remains of the celebrated *Monumentum Ancyranum*, a temple of white marble erected by the inhabitants in honour of Augustus, who improved and embellished the city. On the walls of this temple is an inscription in Greek and Latin, a great part of which is still legible, detailing the principal events in the life of Augustus.—(See *Hamilton's Researches in Asia Minor*, &c., 1842.) Angora has long been celebrated for its breed of goats, which annually yield about 500,000 okes (11,200 cwt.) of hair for exportation. Among its exports are also wheat, opium, gum, wax, and honey. In its vicinity are many fine gardens.

Ancyra originally belonged to Phrygia, and afterwards became the chief town of the Tectosages, one of the three Gallic tribes that settled in Galatia about B.C. 277. In B.C. 189 Galatia was subdued by Manlius, and in B.C. 25 it was formally made a Roman province, of which Ancyra was the capital. On the division of Galatia by Theodosius I. or Valens, Ancyra became the capital of Galatia Prima. It was the seat of one of the earliest Christian churches founded probably by the apostle Paul; and a council was held here in 315. In 1402 a great battle was fought in the vicinity of Ancyra, in which the Turkish sultan Bajazet was defeated and made a prisoner by Tamerlane, the famous Tartar conqueror. In 1415 it was recovered by the Turks under Mahomet I., and since that period it has always belonged to the Ottoman Empire.

ANGORNO, a town of Bornou, in Central Africa, on the south-west bank of Lake Tsad. It is said to have a population of 30,000, which is increased to thrice that number during the weekly markets, when a great traffic is carried on in cotton, amber, coral, metals, and slaves.

ANGOSTURA, a city of South America, in the republic of Venezuela. Lat. 8. 8. 10. N. Long. 63. 55. 20. W. It stands on the south bank of the Orinoco, about 240 miles from its mouth. It is favourably situated for commerce, being in a very fertile district, and the river is navigable for vessels of 300 tons up to the town. In the year 1841–2, 419 vessels entered and left its port, of the aggregate burthen of 29,863 tons. The value of its imports for that year is said to have been L.63,353; of its exports L.115,831. It has a large city hall, an hospital, and a college, and is defended by a fort on the opposite side of the river. Pop. in 1846, 10,000.

ANGOT, a considerable province in the southern part of the kingdom of Abyssinia. See Abyssinia.

ANGOULEME (the *Iculisma* of the ancients), a city of France, capital of an arrondissement of the same name, and of the department of Charente. It stands on an elevated plateau on the left bank of the Charente, 221 feet above the river, and on the railway between Paris and Bourdeaux, 66 miles north-east of the latter. It is the seat of a bishop, a court of assize, and a tribunal of primary jurisdiction; and has a public library, a royal college, an obstetric school, a theatre, a museum of natural history, and a society of agriculture, arts, sciences, and belles-lettres. Angouleme is, in general, well built; but many of the streets in the old town are narrow and crooked. It has numerous paper-mills, a cannon foundry, an extensive powder-mill, manufactories of linen, cloth, and porcelain, besides a considerable general trade, particularly in wine and brandy. The chief public buildings are an ancient castle, a cathedral, and a fine bridge over the Charente. Pop. in 1846, 18,482. The arrondissement of the same name is divided into nine cantons, and 143 communes; and by the census of 1846 contained 136,653 inhabitants.

ANGOUMOIS, an old province of France, now forming the department of Charente and part of that of Dordogne. Its capital was Angouleme.

ANGOY, or Engoy, a small province in the country of Congo, which nearly two centuries ago rendered itself independent. It extends along the northern bank of the Congo or Zaire, from its junction with the sea inwards. A great proportion of the surface is covered with forests and swamps: cultivation has made little progress, and the population is thin. Bomangoi, in the interior, is stated to be the capital; but Cabenda, near the mouth of the Zaire, is the seat of trade, and dealt largely in slaves previous to the prohibition of that traffic.

ANGRA, a city of Terceira, one of the Azores; the capital of that group, and the residence of the governor. It is seated on the southern shore, and its harbour is the only tolerable one in the whole island. It is in the form of a crescent, the extremities of which are defended by two high rocks, that run far into the sea, and render the entrance so narrow as to be easily covered by the batteries on each side. From this harbour the town is said to derive its name; the word *Angra* signifying a creek, bay, or station for ships. Here ships may ride in perfect safety during the summer; but as soon as the winter begins, the storms are so furious, that the only safety is in putting to sea with all possible expedition. Happily these storms are preceded by infallible signs, with which experience has made the inhabitants perfectly acquainted.

The town is well built and populous, and forms the see of a bishop, under the jurisdiction of the archbishop of Lisbon. It contains five parishes, a cathedral, four monasteries, as many nunneries, besides a bishop's court, which extends its jurisdiction over all the Azores. The fortifications have lately been considerably extended. Pop. 13,000.

At Angra are kept the royal magazines for anchors, cables, sails, and other stores for the royal navy, and occasionally

for merchant vessels in great distress. All maritime affairs are under the inspection of the *Desembergador*, an officer who has subordinate officers and pilots for conducting ships into the harbour, or to proper watering places. The English, French, and Dutch, have each a consul residing at Angra, though the commerce of these nations with the Azores is very inconsiderable. Long. 27. 14. W. Lat. 38. 38. N.

ANGRI, a town in the province of Principato Citeriore, kingdom of Naples, with 6400 inhabitants.

ANGUIER, François and Michel, two brothers, natives of Normandy, were distinguished sculptors in the time of Louis XIV. Michel, the younger of the two, executed the sculptures of the triumphal arch at the Porte St Denis. A marble group of the *Nativity* was reckoned his masterpiece.

ANGUILLA, or *Snake Island*, the most northern of the Leeward group. Lat. 18. 14. N. Long. 63. 8. W. Its chief productions are sugar, cotton, maize, tobacco, and salt. Pop. about 3000.

ANGUILLARA, Giovanni Andrea dell', one of the most distinguished Italian poets of the sixteenth century, was born at Sutri in Tuscany about the year 1517. His free translation of the *Metamorphoses* of Ovid in *ottava rima* still enjoys a high reputation in Italy, and some admiring critics have even preferred it to the original.

ANGUINUM OVUM, a fabulous kind of egg, said to be produced by the saliva of a cluster of serpents, and possessed of certain magical virtues. The superstition in respect to these was very prevalent among the ancient Britons, and the traditionary belief on the subject still exists in Wales. This wondrous egg seems to be nothing more than a bead of glass, used by the Druids as a charm to impose on the vulgar, whom they taught to believe that the possessor would be fortunate in all his attempts, and that it would gain the favour of the great.

ANGUS, the old name of the county of Forfar. It gave the title of Earl to the Douglasses; and now to the Duke of Hamilton. See Forfar.

ANGUSSOLA, or Angosciola, four sisters, named Sofonisba, Lucia, Europa, and Anna Maria, distinguished painters, who flourished in the latter half of the sixteenth century. They were members of a noble and ancient family at Cremona. The merit of the younger sisters, though considerable, was eclipsed by that of Sofonisba, who ranks as one of the best portrait painters of that period. She also painted some small historical pieces, which are highly esteemed. She was born in 1533, and was twice married. In 1560, at the invitation of Philip II., she visited the Court of Madrid, where her portraits elicited great commendation. She was blind and infirm at the time of her death, which happened at Genoa in the 93d year of her age. Vandyke is said to have paid her the high compliment of declaring that he had derived more knowledge of the true principles of his art from the conversation of that blind woman than from any other source. She painted several fine portraits of herself, one of which is now at Althorp. (*Vasari; Fuseli's Pilkington; Lanzi.*)

ANGUSTICLAVIA, in *Roman Antiquity*, a tunica worn by the equestrian order, having two narrow purple stripes inwoven parallel to each other, and extending from the shoulders down its entire length. The Laticlavia Tunica, worn by the senators, was loose at the waist, and distinguished by one broad purple band which extended perpendicularly from the neck down its centre. The *Latus Clavus* is said to have been introduced at Rome by Tullus Hostilius after his conquest of the Etruscans, and it appears to have been worn in early times by all classes promiscuously. It seems that Augustus sometimes conferred the privilege of wearing the Latus Clavus on the children of equestrians, as a prelude to entering the senate.

ANHALT, Duchies of, in Germany, lie between Lat. 51. 33. and 52. 7. N., and Long. 11. and 12. 36. E., and comprise an area of 1017 square miles. They are almost entirely surrounded by the Prussian province of Saxony. The country is generally level, having few elevations except where the Hartz Mountains project towards Bernburg. The land, which is in a high state of cultivation, is very fertile, and is watered by the Elbe and its tributaries the Mulde, the Nuthe, and the Saale, which last receives here the Wipper and the Bode. The inhabitants are chiefly engaged in agriculture and the rearing of sheep and cattle, for which the extensive forests and rich meadows are very favourable. The productions of the country are corn, wine, tobacco, flax, hops, and fruits; and its manufactures linen, cotton, and woollen goods, metallic and earthen wares. These find a ready exit by means of the Elbe and the Magdeburg-Leipzig, and the Anhalt-Berlin railways. Game and fish are abundant, and the mountains are rich in minerals.

Anhalt still exists as a consequence of that ancient system of hereditary succession in which the right of primogeniture was not recognised, the younger children sharing also in the heritage. Hence arose those petty kingdoms and principalities, of which several still exist in Germany. Whatever advantages this system may have had, it certainly tended much to retard the diffusion of civilisation and prosperity.

Bernhard, son of Albert surnamed the Bear, was the first who obtained the title of Prince of Anhalt, which territory he held, together with a great part of the Duchy of Saxony On his death in 1211 he was succeeded in the principality of Anhalt by his son Henry I.; while Albert, a younger son, received his possessions in Saxony. On the death of Henry in 1252, Anhalt was divided among his family into three parts, which were afterwards united under Ernest Joachim I., who reigned from 1570 to 1586. On his demise the country was again divided among his four sons into Dessau, Bernburg, Coethen, and Zerbst. The Zerbst family dying out in 1793, their possessions fell to the share of the other three. By the death of Henry Duke of Anhalt-Coethen in November 1847, that line became extinct, and the affairs of the Duchy are now administered by the Duke of Anhalt-Dessau, for behoof of himself and the Duke of Anhalt-Bernburg. In 1807 the princes of Anhalt took the title of dukes, and joined the Confederation of the Rhine. In the Germanic Confederation the three duchies, in conjunction with Oldenburg and Schartzburg, have the fifteenth vote in the ordinary diet; but each has a distinct vote in its plenary assemblies. The population of Anhalt is almost entirely Protestant.

Several of the princes of Anhalt have borne a conspicuous part in the affairs of Europe, and not a few of them have been noted for their zeal in the cause of Protestantism. Wolf or Wolfgang VI., Prince of Anhalt-Coethen, and Joachim I., of Anhalt-Dessau-Zerbst, distinguished themselves in the cause of the Reformation. They were present at the diet of Augsburg in 1530, and Wolfgang was one of those who presented the "Confession" to the emperor.

Anhalt-Bernburg, the most western of the three duchies, has an area of 339 square miles, and is divided into two separate duchies. The upper duchy lies on the side and at the foot of the Hartz Mountains, and though generally mountainous and woody, it has some fine valleys. The lower duchy, situated on the Saale and Elbe, is generally flat, and in some parts marshy. The climate of the lower duchy is temperate and mild, while that of the upper is cold and humid. The mines in the neighbourhood of the Hartz Mountains yield copper, silver, iron, lead, sulphur, and gypsum. It is divided into nine amts or bailiwicks, each of which has a chief town of the same name, viz., Bernburg, Plötzkau, Mühlingen, and Koswick, in the lower duchy; and Bal-

lenstedt, Hartzgerode, Günthersberge, Gernrode, and Hoym, in the upper. The revenue for 1851–2 amounted to 808,888 thalers, about L.121,333, and the expenditure was 806,828 thalers, or L.121,024.

It has some mediatised possessions in the province of Saxony. Pop. in 1849, 50,411; of whom 837 were Jews. This duchy furnishes a contingent of 370 men to the Germanic Confederation, and has a standing army of 300 men. The public debt amounts to 2,100,000 thalers, or L.315,000.

Anhalt-Coethen has an area of 318 square miles, and consists of four distinct parts intermingled with the territories of surrounding princes. The most compact part is that which lies around the capital, and the most distant lies on the right bank of the Elbe. It is generally a level plain, with a sandy soil, but for the most part well cultivated and very productive. It is divided into six amts, viz., Coethen, Neinsdorf, Wulfen, Nienburg, Warmsdorf, and Roslau. Population in 1849, 43,120, almost all engaged in agricultural and pastoral pursuits. The possessions of this duchy in Southern Russia comprise an area of 230 square miles. The principality of Plesse in the Prussian province of Silesia, which was held by the late duke, passed, at his death, to the Count of Hochberg. The revenue and expenditure for the year 1851–2, were respectively 449,888 thalers, or L.67,483. It furnishes to the federal army a contingent of 325 men.

Anhalt-Dessau, the most eastern of the three duchies, has an area of 360 square miles. It is intersected by the Elbe and the Mulde. The greater part of it is very fertile and well watered, and is well cultivated. Population in 1849, 63,700. Its mediatised possessions have an area of about 200 square miles, with 12,000 inhabitants. It is divided into seven amts, viz., Dessau, Oramnibaum, Quellendorf, Gröbzig, Sandersleben, Alsleben, and Zerbst, each of which has a chief town of its own name. It furnishes a contingent of 529 men; and its revenue and expenditure are equal, each being in 1851–2, 596,000 thalers, or L.89,400. Anhalt Dessau and Coethen have a standing army of 1000 men; and a public debt of 3,500,000 thalers or L.525,000, of which last rather more than two-thirds belongs to Coethen.

ANHOLT, a Danish island in the Cattegat, 32 miles north-east of Greenæ, and 36 south-east from Lessoe. It is a barren spot, scarcely affording subsistence to 200 inhabitants, who, from their language, which is Celtic mixed with a few Danish words, are supposed to be emigrants from the Highlands of Scotland. Their chief pursuit is fishing. The occupation of this island was a subject of contest with England during the war. It is surrounded by dangerous banks of sand, for which reason a lighthouse is built on its most easterly promontory, in Lat. 56. 44. 20. N. Long. 11. 38. 51. E.

ANIANI Breviarium. See Civil Law.

ANICHINI, Luigi, an engraver of seals and medals, born at Ferrara in the sixteenth century. Michael Angelo pronounced his *Interview of Alexander the Great with the High-Priest at Jerusalem* "the perfection of the art." His medals of Henry II. of France and Pope Paul III. are greatly valued.

ANIELLO. See Massaniello.

ANIMAL. See Animal Kingdom.

Animal-Flower, a name applied to certain species of the genus *Actinia*, remarkable for the brilliant colours which ornament their tentacula, and which produce an appearance resembling the variegated corolla of a plant. The name is of vicious construction, and is falling into disuse. See Zoophytes.

ANIMAL KINGDOM.

We embrace the earliest opportunity afforded by our alphabetical arrangement to present a few introductory observations in illustration of a science unrivalled in interest, and not greatly surpassed in importance by any department of human knowledge. Zoology, or the science which treats of the nature and history of animals (from ζωον, *an animal*, and λογος, *a discourse*), embraces so vast a field of observation, that although it cannot be regarded otherwise than as a single and beautifully connected science, its great extent of general doctrine, and multiplied variety of details, render necessary a subdivision into many branches, each of which, if worthily followed, is in truth more than sufficient to occupy the undivided attention of the most zealous votary. If in voluminous works exclusively devoted to natural history a single department of the science usually engrosses the entire attention of an author, it is evident that, in the present publication, it would not only be in vain to attempt a complete exposition of the subject under a single head, but that even the various treatises under which its different branches will be exhibited must be presented in a very abridged and compendious form. It shall be our endeavour, however, in the course of our natural history treatises, so to select and methodize the great leading facts of the science, as to enable our readers to form an accurate idea of the present state of zoological knowledge, even though certain minuter details, hitherto forming too conspicuous a feature of the subject, yet not essential to its truthful representation, should in some measure be curtailed.

With a view to obviate to a certain extent the inconvenience arising from the disconnection of the different parts of the science, which the nature of an alphabetic encyclopædia necessarily occasions, we now propose, under the words *Animal Kingdom*, to give 1*st*. an exposition of such of the general doctrines of zoology as, not pertaining more to one department than another, may with the greater propriety be separated from the history of particular classes, and presented as a useful and appropriate introduction to the whole,—thus uniting the advantages of an alphabetical and systematic arrangement; 2*dly*, to present outlines of some of the prevailing systems of zoology, so as to exhibit in a condensed form the general principles of classification, and enable the student more clearly to understand the relative connections which exist between the scattered treatises in which the subjects (in their alphabetical order) will be afterwards more fully developed; and 3*dly*, to give a sketch of the arrangement to be followed during the future progress of this work, which will not only serve as a guide or general index to the separate articles, but will, on the completion of the Encyclopædia, enable the attentive reader to methodize these articles in such a manner as to form a complete and consistent system of zoology.

It is by no means so easy as it may at first appear, to define precisely what is meant by the term *animal*, because, as we descend in the scale of beings, we find a transition so gradual from those whose powers and properties are strongly characterized, to others which, along with a scarcely perceptible share of sensation and voluntary motion, partake so greatly of the nature of plants, that the most acute naturalists have varied in opinion regarding the exact line of their demarcation. There are also many plants which appear to differ less from certain animals than they do from other plants of an opposite nature and construction. This connected series of organized bodies, however, is not graduated after the mode established by some vague writers on natural history

for it is not the most perfectly composed, but rather the least complex plants, which follow the most simply organized animals. It has been said that nature follows a continuous and ascending chain, from the mineral to the plant, and from the vegetable to the animal kingdom, the apex of which is crowned by the most perfect work of creation,—the human race. Certain minerals, such as amianthus or asbestos, no doubt exhibit a fibrous or woody structure; and coral, which has a stony texture, a vegetable form, and polypus inhabitants, has been adduced in illustration of the union of the three kingdoms.[1] But all such fanciful speculations are the result of partial and inaccurate observation. The calcareous basis of the coral is formed by a species of polypus, and has no more principle of increase in itself than the shell of the oyster or the waxen cells of the honey-bee. Its elegant branches are created by the instinctive labours of the animal inhabitants, which alone are possessed of life. The animal and vegetable kingdoms are more correctly compared to two great pyramids, intimately united at their bases, but diverging more and more as they ascend.

The extraordinary beings which by their ambiguous nature may be said to have thus blended two kingdoms into one, are called zoophytes or animal plants. They were arranged by Tournefort among vegetables, and were at an after-period removed to the class to which they really belong, chiefly on the authority and through the labours of Linnæus and Pallas. These naturalists bore in mind what few of their predecessors seem to have remembered, that locomotion, that is to say, the movement of a body from place to place *en masse*, though a general characteristic, is not an essential or indispensable attribute, of animality; for numerous animals of the molluscous and radiated kinds are as permanently fixed to their native rocks and coral reefs as the most deeply rooted plants are to the soil which gave them birth.

As sensation and the power of voluntary movement, in whole or in part, are the principal characteristics of animals, it is evident that the more these faculties become developed, the greater will be their removal from the vegetable kingdom. The more perfect the plant, and the more complicated the animal becomes, the greater disparity will be perceived to exist between them. If, in distinguishing the animal from the vegetable, nothing more were required than to point out the differences between an oak and an elephant, the line of demarcation would be easily drawn, and the characters of the respective classes could never more be confounded. But there are many plants which, though less aspiring than the oak, lay claim to a closer alliance to a higher kingdom; and many animals of a more carnivorous nature than the elephant are much more nearly connected by their nature and attributes with the vegetable tribes. When we perceive a living or animalized substance producing by suckers, buds, or offsets from its own body,—when we see that by the influence of light, air, and humidity, it is rendered capable of re-assuming the functions of vitality after a long period of suspended animation and apparent death,—when we ascertain that it cannot live except in water, or when saturated with moisture,—and that although it may be capable of certain languid and partial motions, it is yet fixed for life to a single point of space, where it derives its nourishment by means of external pores,—we have certainly the description of an animal of the lowest order, which applies at the same time almost equally well to vegetable life.

The following were the dicta of Linnæus in relation to the three kingdoms of nature:—"Minerals grow; vegetables grow and live; animals grow, live, and feel." The only character common to these kingdoms, according to the above definitions, is that of growth, or the power of adding to previous bulk. "The vegetation of stones," it is observed by the late bishop of Llandaff, in his *Chemical Essays*, "hath been admitted by many; and some have contended that minerals, as well as animals and vegetables, *spring from seed*, the greatest being nothing but the expansion of the parts of a minute grain of sand." But mineral bodies in truth cannot be said to grow. They receive by aggregation or superposition, by mechanical or chemical agency, an increase of particles. Tournefort, indeed, was of opinion that stalactites in caves actually increased by an internal growth or propulsion like that of plants and animals. But it is known that these concretions add to their bulk by successive depositions of stony particles contained in the water which bathes their sides or percolates through the canal by which their centres are frequently perforated. They possess no attribute which bears the slightest affinity to that internal life which propels the fluids or assimilates the nutritive juices in the animal and vegetable kingdoms. Minerals, then, are destitute of that active power by which animals and plants effect an individual appropriation of such materials as conduce to their nourishment and increase, and which is carried on, not by casual juxtaposition, or the addition of similar particles previously prepared, but by an admirable and elaborate process, through which the ponderous bullock, with its immense load of fleshy fibre, converts into its own muscular and sanguiferous system the sweet-smelling grass of the meadow; and through which also the size and flavour of our most delicious fruits are often primarily derived, from an addition to their natural soil of substances of a very different and less inviting nature. Romé de Lisle has accurately observed that straight lines and plane surfaces are characteristic of mineral bodies, but that animals and plants are composed of curved lines or rounded surfaces, resulting from that central power of life which dilates the internal organs in all directions, and tends to produce spherical or cylindrical forms. The seeds of plants, the eggs of birds, and the young of all animals, are remarkable for the roundness of their outlines.

The objects of natural history, however, are not now divided into three kingdoms; for the characters which connect together plants and animals on the one hand, and distinguish both of these kingdoms from minerals on the other, are so obvious and strongly marked, that the divisions now established are those of *organic* and *inorganic* bodies; the former including all animals and plants, the latter all mineral substances. The definition of an animal, given by M. Virey, is as follows: *A being, organized, sensible, endowed with voluntary motion, and provided with a central organ of digestion.* And he thus defines a plant: *A body, organized, insensible, not endowed with voluntary motion, nourished by external pores.* To these he adds another character, that the reproductive organs of plants are developed and thrown off every year, whereas those of animals are persistent. It is evident that the last clause of his first definition—that which relates to the central organ of digestion—if rigorously applied, would exclude a number of the infusorial tribes from the animal kingdom.

Perhaps the most efficient mode of distinguishing between animals and plants is by having recourse to a certain range of characters, derived from the study of their

[1] Virey, *Mœurs et Instinct des Animaux.*

internal structure and organic functions: thus the possession of nerves, muscles, and a stomach, with the consequent attributes of *sensation*, *voluntary motion*, and *digestion*, will be found to separate animals properly so called from all other organized matter. If these leading characters are not common to all animals, they are at least proper to them alone; and if the whole of these characters are not always united in the same animal, we invariably find at least one of the three. Thus certain species of polypus, the sensibility and voluntary movements of which cannot be said decidedly to manifest themselves, are obviously furnished with a digestive cavity or stomach; and many of the infusory animals, of the digestion of which we know nothing, are as perfect in regard to their varied powers of locomotion as any of the higher classes. Numerous zoophytical species, indeed, are of so simple a nature, that in them we cannot perceive either a distinct tissue or a nourishing fluid; but we can form some opinion of the nature of their elements from the character of their properties. Irritability indicates nerves, motion supposes the existence of muscles, and the continued maintenance of life attests nutrition. Thus the materials of animal life, so vaguely constituted in these creatures, are detected by their general properties.

In relation to their chemical characters, animals may be said to be principally composed of azote; and vegetables, with the exception of cruciferæ, of carbon. Animals absorb oxygen, plants disengage it; the former reject carbon, the latter become impregnated with it. An exchange of principles is thus effected between the two great divisions of organized existence; but it has been observed that plants merely fix or organize carbon, whereas animals appear to transform into azote, both the air which they respire, and the aliments by which they are nourished.

It has been asserted that a *single mouth*, or opening to the digestive canal, sufficiently characterizes animals from plants, as the latter always possess innumerable pores, which with them are the representatives of the mouth, and conduce to the same ends; but this distinction is in fact inaccurate, as some species of Fasciola possess two mouths, certain Tristomæ three, and the genus called by Cuvier Rhisostoma many more; to say nothing of the infusorial tribes, many of which have no mouth at all, but derive their nourishment by imbibition through the medium of external pores. Nutrition, or the power of deriving nourishment from other bodies, is common alike to plants and animals, and effects for organized and living bodies that increase of bulk which inorganic or disorganized substances can only attain through the medium of an affinity of particles, or by mechanical aggregation. The functions of nutrition, however, as manifested in the animal and vegetable kingdoms, are very differently performed in each. Fixed for ever to the soil which gave them birth, plants are rendered incapable of searching after nourishment by a voluntary change of place, but derive their chief support from roots, the pores of which absorb the nutritive portions from the humid soil, and by a uniform and continuous action, which is only interrupted by an absence of the necessary moisture. The generality of animals, on the contrary, being possessed of the power of locomotion, are also endowed with the capacity of transporting with themselves a supply of necessary nourishment; for which purpose they are provided with an internal cavity or stomach, the inward surfaces of which are provided with absorbing pores, which Boerhaave expressively named *internal roots*. "The magnitude of this cavity," observes Cuvier, "in a number of animals, permits them to introduce solid substances into it. It was necessary then that they should have instruments for dividing those substances, and liquors for dissolving them. In a word, with such animals nutrition does not immediately commence upon the absorption of the substances which the soil or the atmosphere furnishes. It is necessarily preceded by a vast number of preparatory operations, the whole of which constitute *digestion*."[1] The motion of the nutritive fluid in plants, from the simplicity of their structure, and the fixity of their position, seems to be preserved by simple external agents. "It appears to proceed upwards by the effect of their spongy or capillary texture; and the evaporation which takes place at their top, and its motion in that direction, is the more rapid in proportion as the evaporation is great. It appears also that the motion of this fluid may even become retrograde, when it ceases to flow in its usual course, or changes into absorption by the coldness and humidity of the atmosphere."[2] In regard to animals, however, the case is different. Being destined continually to change their localities, and to live exposed to a variety of temperatures, they require an active principle within themselves for the conveyance of their nourishing fluid. This fluid is therefore contained in a multiplicity of canals, which are ramified from two trunks, communicating with each other in such a manner that the roots of the one, called the venous system, receive the contents which the other, known as the arterial system, has propelled to the extremity of its branches, and restore them to the centre, from which they are again driven forward. It is this rotation which constitutes what is called the circulation of the blood. It may be regarded as a function of a secondary order proper to animals, but not universal to that kingdom, as it depends in a great measure on the existence of that central organ called the heart, of which some classes are entirely destitute. It is therefore less essential to life than digestion, and not so intimately related to the faculties of sensation and locomotion. In regard to respiration, animals which are unprovided with a regular circulating system respire, like vegetables, over the whole of their surface, or by various vessels which are placed at different points, and convey the air to the interior of their bodies. "No animals," says Cuvier, "respire by a particular organ, except such as have a real circulation; because in them the blood coming from one common source, the heart, to which it constantly returns, the vessels that contain it are so disposed that it cannot arrive at the other parts until it has passed through the lungs. This, however, cannot take place in vegetables, or in those animals in which this fluid is everywhere diffused in a uniform manner, without being contained in vessels." Pulmonary or branchial respiration is therefore an animal function of a third order, invariably connected with circulation, and one degree removed from such faculties as are essential to animal life.

When a vegetable dies of old age, it begins to decay in the centre. We frequently see ancient willow-trees entirely dead, except in a few slender twigs, or in small portions of their superficial bark. An animal, on the contrary, first dies in its extremities and circumference, whilst the heart or central portion continues for a time to perform, however languidly, its accustomed actions.

Among plants both sexes usually occur in the same individual, or even on the same flower; but in a far greater proportion of animals the two sexes are represented by separate individuals. There is indeed no genuine hermaphrodital union among mammiferous animals, birds, reptiles, fishes, cuttle-fish, crustacea, or in-

[1] *Lectures on Comparative Anatomy*, lecture i.

[2] *Ibid.*

sects. Among many molluscous animals, however, such as the oyster and other bivalves, both sexes are found on the same individual, which is consequently sufficient of itself for the purposes of reproduction, and may be regarded as a genuine hermaphrodite. This singular order of things is in fact indispensable to the nature of bivalve testacea, which, being almost entirely deprived of the power of locomotion, and destitute of eyes or other organs by which to distinguish each other, require to possess within themselves the power of reproduction, lest their kind should cease. The species is both represented and continued by a single individual. In the earthworm, again, the same union of the sexes occurs, but modified in such a way that the concurrence of two individuals is required for the continuance of the race, and each acts in relation to the other both as male and female. This is also the case with slugs, and a great proportion of univalve and turbinated shells. Lastly, the zoophytical animals are not distinguished by any sex, but are multiplied by separation or excision of parts of their own bodies.

The law which establishes a perfect distinction and separation of the sexes in animals seems likewise to produce a double and symmetrical structure, and is of great extent in that kingdom; whilst the circular or radiated form more especially distinguishes plants, and is also characteristic of those zoophytical tribes which, both by name and nature, claim an alliance to the vegetable world.

The grain, and the fruit or kernel, may be said to bear the same relation to a vegetable as the egg or the embryo does to an animal,—with this difference to be borne in mind, that the concurrence of the sexes is necessary to the formation of the vegetable egg, whereas in the animal kingdom that circumstance is indispensable only to the fecundation of the pre-existing germ. The perfection of a plant, and the ultimate aim of its existence, if we may use such a phrase to an inanimate structure, consist in the continuance of its kind. In such as are named *annuals* especially, the term of whose existence is limited in many instances to a small portion of the year, the ripening of the seeds is speedily effected, and, after a very brief period, death succeeds " the bright consummate flower." In numerous tribes of insects the same fleeting existence is observable, though the ephemeral nature of these last-named tribes is rather apparent than real, as the wonderful metamorphoses to which they are subjected conceal their identity from the eye of the uninitiated, and greatly interfere with a continuous tracing of the same individual from the egg to the perfect form. For example, many aquatic flies, such as the Ephemeræ and others, whose declared and more obvious existence does not exceed a few hours, have, previous to their assuming the winged state, spent months or even years in the banks of rivers, and beneath the surface of the stream.

Even the mode of reproduction among the lower tribes of the animal kingdom bears some analogy to that of vegetables; and as the vital principle in the smallest branch or portion of a willow-tree is easily continued and increased though separated from the parent stem, so in many zoophytical animals a bud, branch, or other section, removed from the full-grown individual, suffers no injury from such partition, but, on the contrary, acquires almost immediately a complete and independent power of existence within itself, and is ere long capable of exercising or enduring a like division in favour of posterity. Animals as well as plants are liable to be affected by the revolutions of the seasons; for the period of flowering in the one class is answered by the season of love in the other, and the fall of the leaf is only analogous to the periodical renewal of the feathers of birds and the hair of quadrupeds. The platanus quits and renews its superficial bark, while serpents and cray-fish cast off and reproduce their scaly and crustaceous covering. To be produced and nourished, to increase, to engender, and to die, are characters common to every class of organized existence; but animals properly so called are alone endowed with instinct and voluntary motion,—they alone possess nerves, muscles, digestive organs, and blood, with the faculties of perception, &c. consequent on these attributes.

The preceding observations will serve to illustrate the principal relations and analogies which exist between animal and vegetable life. But there are other characters proper to animals, the whole of which, however, are not universally bestowed on that class, of which it will now be proper to say a few words. The substance of which even the most perfect animal is composed may be resolved into four *tissues*,—the *cellular*, the *muscular*, the *fibrous*, and the *medullary*.

The cellular tissue is the most extensively bestowed, and forms, according to an expression of the French physiologists, the *canvass* of all the organs, and of every animal. It is even common to vegetables, and serves at once to compose, to unite, and to separate the organs. Formed of laminæ or plates interlacing each other in every direction, and perforated by small cavities which have intimate communication, it also sometimes presents itself under the form of membranes, which, when they assume a tunnelled or cylindrical shape, are denominated vessels. It is in this tissue that the gelatine accumulates for the formation of the cartilages, and the calcareous salts for that of the bones. It is amongst its meshes that the fat is amassed, the small vessels distributed, and warmth developed. It forms the basis of the organs.

The muscular tissue is composed of fibrin, and its chief property is that of contraction. It forms what are called the fleshy parts of bodies. Bundles of this tissue crossing each other compose the heart, and, under another aspect, form the stomach and intestines. It is the agent of movement.

The medullary or nervous substance is composed of a soft albuminous pulp, and is protected by powerful membranes. It enjoys the admirable faculties of perceiving, comparing, judging, remembering, and willing; it gives to the senses their special properties, to the muscles their moving force, and is the seat of that mysterious union between mind and body through which the intellectual faculties result or become manifested, and the exact nature of which the most acute of metaphysical inquirers, and the most accurate and thoughtful observers of nature, have as yet sought in vain to illustrate. Sensation is the attribute of the nerves.

The fibrous tissue, the most resistant and unfeeling of all, fastens the bones to each other, and connects the bones and the muscles. It forms the ligaments, the tendons, many vessels, and some resisting membranes employed for the protection of the more important organs. In composition it approaches the cellular tissue, but its properties are dissimilar. Its character is resistance.

Each of these tissues is destined to the performance of a special purpose: The cellular organizes, the muscular moves, the nervous perceives, the fibrous attaches and resists; but one and all are under the influence of that nourishing fluid, so different in various animals, known by the name of blood. This fluid is red, circulating, of a high temperature, in animals of the superior classes—that is, the mammalia and birds; less red, colder, and not so charged with oxygen, in fishes and reptiles; colourless, but still circulating, in the mollusca; without either colour or movement in insects; scarcely perceptible in certain worms; and apparently wanting in zoophytes. It is this fluid which animates all the organs, and presides over

every function. Nutrition exhausts its principles, digestion repairs them, respiration elaborates and renders it perfect, and the action of the heart gives it circulation.

All these elements united and variously combined compose the different organs of animated beings, the harmonious action of which organs forms the essence of our wellbeing, physically considered, in the present stage of our existence. The human race possesses the attributes of animal life in common with the brute creation; but we must ever bear about with us a firm conviction that these are "the accidents, not the essentials of our nature;"[1] and that however proper it may be to mention them as the technical statements of physiology, yet that they are totally inadequate to the description of a being who bears about with him the germ of immortal life, and knows that he was created "but a little lower than the angels." "Those persons," says Buffon, "who see, hear, or smell imperfectly, are of no less intellectual capacity than others; an evident proof that in man there is something more than an internal sense. This is the soul of man, which is an independent and superior sense, a lofty and spiritual existence, entirely different in its essence and action from the nature of the external senses."

It is easy to perceive that one set of organs may be so related to another as constantly to require its co-existence. Thus, circumscribed respiratory organs are always accompanied by a heart, which causes the blood to flow through them; and a brain is never found without nerves and muscles, which serve it as faithful ministers and attendants. The brain receives impressions, and is enabled to judge of them through the medium of nervous sensations: this is the first mode of the functions of relation. But the order is inverse so far as relates to the phenomena of the will as connected with the exercise of the voice and the organs of movement. The brain wills or commands, the nerves transmit the order, and the muscles execute it.

There are other co-existences in the animal economy as apparent as those above alluded to, the motives of which are not, however, so easily comprehended. We are still ignorant why the viscus called the liver should always exist where there is a heart; and why all orthopterous insects should have the forehead furnished with a broad plate.

It will readily be conceived that the diversified circumstances of life in the various tribes of animals necessitate an infinite variety of phenomena in their functions and faculties. An animal which respires, and has its dwelling in the waters, can neither feel nor move after the manner of one which breathes in the pure air; and wherever there are branchiæ or gills instead of lungs, we are sure also to find oviparous generation, an incomplete circulation, an absence of voice, and imperfect organs of hearing and of smell. But the existence of lungs alters the relation of the whole of these functions.

The same principle may be applied to the different kinds of aliment. A carnivorous animal is endowed with force and courage: it has a strait stomach, short intestines, and a lank or somewhat slender form. Herbivorous animals, on the contrary, are usually mild and timid, dull in action, of a sluggish nature, and unapt to self-defence: their intestines are spacious, and their external forms more or less massive. "The disposition of the alimentary canal determines, in a manner perfectly absolute, the kind of food by which the animal is nourished; but if the animal did not possess, in its senses and organs of motion, the means of distinguishing the kinds of aliment suited to its nature, it is obvious that it could not exist. An animal, therefore, which can only digest flesh, must, to preserve its species, have the power of discovering its prey, of pursuing it, of seizing it, of overcoming it, and of tearing it in pieces. It is necessary then that this animal should have a penetrating eye, a quick smell, a swift motion, address and strength in the jaws and talons. Agreeably to this necessity, a sharp tooth, fitted for cutting flesh, is never co-existent in the same species with a hoof covered with horn, which can only support the animal, but with which it cannot grasp any thing: hence the law according to which all hoofed animals are herbivorous, and also those still more detailed laws, which are but corollaries of the first, that hoofs indicate molar teeth with flat crowns, a very long alimentary canal, a capacious or multiplied stomach, and several other relations of the same kind."[2] In short, such harmony exists between the different organs, according to the leading forms after which they are modelled, that an experienced anatomist, from an inspection of a very limited portion of a body, can form an accurate opinion regarding the entire characters of an animal. It is thus that Cuvier, combining profound knowledge of detail with a commanding power of generalization, has, as it were, called back into existence those long-extinguished races whose scattered and imperfect remains attest the wonderful revolutions to which our planet has of old been subjected.

The aid which natural history has derived from the sister sciences of anatomy and physiology, is in nothing more apparent than in the improved systems of modern classification. It was formerly the practice to adopt, as the basis of arrangement, the modifications of some single organ, chosen arbitrarily and at hazard. Of course it did not follow that all the other organs would resemble each other in all the animals in which the likeness of this one organ might be preserved. Nothing, therefore, could be affirmed respecting the other organs belonging to the whole of a class or genus of animals, which we should have attempted to distinguish by characters taken from this unimportant organ. "Suppose, for example," says Cuvier, "that we had made three divisions of animals, the aerial, terrestrial, and aquatic, as they were anciently classed; there would be included in the first class, besides what are commonly called birds, some mammiferous animals, such as bats—some reptiles, as the dragon—some fishes, as the flying fish—and an infinite multitude of insects. Similar difficulties would occur, in a greater or less degree, in the other two classes." "This example is well calculated to show how important it is that the characters of our divisions should be well chosen; for, though in the formation of methods and systems of natural history, errors so flagrant as the above are not now committed, several naturalists, even in modern times, have adopted divisions which, in the detail, tend to similar results."[3]

It is both interesting and important to trace the different systems of organs in the animal kingdom, from their first feeble rudiments, through a gradual and long-continued chain of increasing manifestation, to their complete development in some particular class or order, in which the perfect exercise of a special function is indispensable to its wellbeing. It is in accordance with such development that the improved classifications of recent times have been established; and it is now admitted as an axiom, that a natural and philosophical arrangement of animals can have no other foundation than a knowledge more or less perfect of anatomical structure. It does not follow from this that every naturalist must be a profound

[1] Grinfield's *Letters to Laurence*. [2] *Lectures on Comparative Anatomy*, vol. i. p. 56. [3] *Loc. cit.* p. 62.

anatomist; for such is the multiplicity of details connected with the history of the haunts and habits of species, and with the discrimination and description of their external characters, which in truth form the proper object of the zoological inquirer, that a much longer period than that allotted to the life of man would be required likewise to ascertain the distinctions of internal structure, were it necessary to apply anatomical science to all the minor details, or even to the less important divisions, of natural history. But the beauty and excellence of the anatomical system consists in the admirable co-ordination of characters which it exhibits, and through which, with rare exceptions, we are able to arrange the subjects of investigation in a natural manner, even according to their external aspect, as soon as we have established certain great leading principles of classification drawn from the facts of anatomical science. The more essential and important characters even of internal structure are manifested externally by the influence which they exert over more obvious though less dominating attributes; and thus, even in the absence of a positive and direct knowledge of general laws, these are indicated with wonderful certainty, though somewhat empirically, by means of superficial observation. It is thus that, through the combined efforts of the naturalist and anatomist, the convenience and facility of application which characterize artificial systems, and constitute indeed their sole value, may be combined with that philosophical accuracy and consonance with the march of nature which results from deeper and more substantial views.

The object of every good method, according to Cuvier, is to reduce a science to its simplest terms, by reducing the propositions it comprehends to the greatest degree of generality of which they are susceptible. A good system must therefore be such as will enable us to assign to each class, and to each of its subdivisions, some qualities common to the greater part of the organs. This object is to be attained by two different means, which may serve to prove or verify one another. "The first, and that to which all men will naturally have recourse, is to proceed from the observation of species to uniting them in genera, and to collecting them into a superior order, according as we find ourselves conducted to that classification by a view of the whole of their attributes. The second, and that which the greater part of modern naturalists have employed, is to fix beforehand upon certain bases of division agreeably to which beings, when observed, are arranged in their proper places. The first method cannot mislead us, but it is applicable only to those beings of which we have a perfect knowledge; the second is more generally practised, but it is subject to error. When the bases that have been adopted remain consistent with the combinations which observation discovers, and when the same foundations are again pointed out by the results deduced from observation, the two means are then in unison, and we may be certain that the method is good."

The true distinction between the value of an artificial and of a natural method in zoology consists in this, that the former teaches us little more than the name of an animal, whereas, in relation to the other, we have no sooner ascertained the name of a species, o. its position in the system, than we become at the same time acquainted with numerous facts in its character and history, which we never could have discovered, except by actual observation, had it formed part of those miscellaneous and falsely connected groups which so often constitute the divisions of an artificial system. A natural arrangement is also of great advantage in facilitating general views, by rendering a single animal a type or representative of many, as containing in itself the essential characters of a numerous tribe; and thus the whole animal kingdom may be represented by a few hundred species. By a too strict adherence, however, to the natural method, we are apt to lose the advantage of precision in individual definitions, and, in the case of the numerous transitions, find ourselves unable to fix any limits, if these have not been already established by nature. To discover a medium between these two methods, so as to unite the advantages of each, is now more than ever desirable in the formation of systems.[1] He indeed who flatters himself with the idea that the families, tribes, genera, and sections, which he has laid down on paper, are so many natural divisions, can only be compared to the person who, because he may find the meridians and other circles of an armillary sphere convenient for the division of the heavens, should therefore imagine that they must exist in nature. "In one and the other case," Mr Macleay observes, "artificial modes of distribution are resorted to, which, however ingenious in themselves, are but sad proofs of the limited state of our faculties, when we consider, that without such instruments the vastness and sublimity of the creation cannot be comprehended." (*Horæ Entom.*) There is in fact no such thing as classification in nature. In the animal as well as in the vegetable kingdom certain species are grouped together by such analogies of form and structure, as to render their mutual resemblances apparent even to an ordinary observer. To these groups the name of natural families may, without impropriety, be applied; but that no general system of arrangement exists in nature, by which the various genera may be made to follow each other, like the links of a linear chain, is evident from the discordant, ever-varying, and frequently arbitrary methods employed even by the most accomplished naturalists of the day. We must probably rest satisfied with such a system as presents the objects of natural history in conveniently arranged groups, the component parts of each of which bear a considerable resemblance to each other, without seeking after what is unattainable, namely, the establishment among these groups of a perfectly natural and well-graduated sequence. "When there are," says Mr Vigors, "no absolute divisions except species in nature—and this, from every observation I have been enabled to make, I firmly believe to be the case—every division which we are forced to institute in our arrangements for the convenience of illustration, and indeed for the purpose of mutual communication with those who are engaged in similar researches with ourselves, must be to a certain extent arbitrary and artificial; and every inquirer into nature may cause the line of demarcation that separates his conterminous groups to infringe more or less on the limits of either, according to his peculiar mode of viewing his subject."[2]

No satisfactory argument can be adduced to prove, as some have imagined, that the specific differences of animals have resulted from the lapse of time, and the effects of climate, or other secondary causes. The variation of specific character, though sometimes remarkable, is restricted; and Cuvier has shown, from a minute examination and comparison of mummies of the ancient Egyptian Ibis with individuals of the modern race, that in regard to that species no perceptible change has taken place during the last three or four thousand years. The original creation of distinct and predetermined species is the rational and well-founded belief of all who have studied the

[1] See Carus's *Introduction to Comp. Anat.*, translated by Gore.

[2] *Linnæan Transactions*, vol. xiv. p. 512.

subject with attention, unbiassed by any prejudice in favour of imaginative views, which have no foundation in the facts of nature. " It is certain by revelation," says Buffon, " that all creatures have equally participated in the favours of creation; that the first two of each species were formed by the hands of the Creator; and we ought to believe that they were then nearly such as they appear at present in their descendants. We must also consider, that although nature proceeds by gradual, and frequently by imperceptible degrees, the intervals are not always the same. The more exalted the species, the fewer they are in number; and the shades by which they are separated are more conspicuous. The smaller species, on the contrary, are very numerous, and have more affinity to each other, so that we are the more tempted to confound them together in the same family. But we should not forget that these families are our own works; that we have made them for the ease of our memories; and that if we cannot comprehend the real relations of all beings, it is ourselves, not nature, that are in fault; for she in truth knows not our pretended families, and recognises individuals alone."

Omnipotence, the first, the greatest, and indeed the only truly creative power, formed the species of animals; and the influence of man and of physical agents has produced the varieties. But it is only superficial characters which either the one or the other of these ulterior causes has the power of modifying. The basis of organization, or real specific mould, remains unalterable, though a thousand circumstances constantly tend to produce variations in the external forms. Of these circumstances the most powerful is no doubt climate; under which name it is necessary to comprehend the differences of local situation and temperature, the nature of the soil and its productions. It is climate, in the first place, which chiefly determines the geographical position of animals, and thus commences the action of the modifying powers. The nature of their food is also highly influential; and as it depends so immediately on the qualities of temperature and soil, the climate is still the modifying cause. If the same animals usually accompany the same vegetables, it is because the constitution of both demands similar influences, and because through each other they are both dependent upon the same support. Certain animals are leagued with certain plants, and these again with certain soils and climates; and a careful observance of these mutual dependencies exhibits one of the finest and most beautiful harmonies of nature. This, however, is not the place in which to discuss the intricate and important subject of the geographical distribution of animals.

Certain original forms have been continued since the creation of organized beings, and all the *individuals* which represent or belong to one of these forms constitute what is called a *species*. The slighter differences which occasionally prevail among the individuals themselves, independent of the customary distinctions of age and sex, are called *varieties*. Such varieties are seldom permanent, and are usually lost by the progeny re-assuming the ordinary and characteristic form or colour, except in some remarkable instances, such as the horse, dog, and other long-domesticated species, of which man has so thoroughly altered the original condition, as to have impressed them with a second and more pliant nature. An individual, according to Buffon, is a separate detached being, and has nothing in common with other beings, excepting that it resembles, or rather differs from them. All similar individuals which exist on the earth are considered as composing the species of those individuals. Yet it is neither the number nor collection of similar individuals which constitutes them; for a being which existed for ever would not be a species. " Species then is an abstract and general term, the meaning of which can only be determined by considering nature in the succession of time, and in the constant destruction and renewal of beings;" and it is by comparing the present state of nature with the past, and actual individuals with their predecessors in kind, that we come to attain a clear idea of what is called species; for a comparison of the number or resemblance of individuals is only an accessory idea, and frequently independent of the first. The ass resembles the horse more than the barbet the greyhound; yet the latter are but one species, since they produce a fertile progeny; but the horse and the ass are certainly of different species, " since they produce together vicious and unfertile young."

It is indeed difficult to define the term *species*, otherwise than as an assemblage of individuals descended from common parents, which bear as great a resemblance to them as they do to each other. Species then are distinguished by fixed forms, which, though to a certain extent alterable, and for a limited time, by external or accidental causes, are yet handed down unimpaired from generation to generation; and although certain species seem to have disappeared entirely from the earth, in consequence of the great natural catastrophes which have taken place in ancient times, and the local distribution of many still existing races has been modified or changed by the influence of man no less than by the accidents of nature, there is no reason to believe that any one species has sprung from the gradual alteration of another, or that the circumstances under which an individual may have been at first casually placed were sufficient to develope both form and function, without an impress from a higher and more powerful hand, by which it was fitted to perform its part (pre-ordained) in the great theatre of the world.

Animals which by their union produce *fertile* individuals, are generally reputed of the same species. This law of nature, as it was formerly called, having been found to admit of certain though rare exceptions, is not now so broadly insisted on as a test of specific identity as it was in preceding times. But it appears, from the result of numerous experiments, that the generality of animals produced from a cross between even the most nearly allied species, are either altogether incapable of reproduction, or fertile in so imperfect a degree, that their descendants speedily become entirely sterile. It has been said that birds alone were unsubjected to this rule, and that hence has arisen the wonderful variety which that beautiful class exhibits. There is no doubt of the occasional fertility of their hybrids, as in the case of those mule birds produced between the goldfinch and canary; but as it has not been proved that such unions of distinct kinds ever take place when uncontrolled by the depraving influence of domestication, there is no reason to attribute the origin of any of those species or varieties which are known to exist in a wild state to any such improbable alliance.

It is known that a productive union may take place between animals of a different species, provided such species belong to what naturalists call the same natural family. Thus the ass and the mare, or the horse and the female ass, produce the well-known animals called mules: the zebra also produces both with the horse and the ass; but in order to deceive the female zebra, it is said to be necessary to paint the hides of the former with those bizarre colours which adorn her accustomed mate.[1] It is probable,

[1] *Dict. Class. d'Hist. Nat.* tome i. p. 48.

however, that all these unions are so far forced and unnatural, that they never take place except through the influence of man, when domestication, and the numerous changes consequent upon it, have altered or impaired their natural instincts; for it has been observed that, however education may perfect certain special qualities, which man has the art to render subservient to his own convenience, yet a more extended view of the effects of domestication will convince us, that it is almost always to the disadvantage of their natural capacities that the brute creation are made to borrow the mask of human intelligence.

Buffon appears to have adopted from Ray a rule which many now regard as inaccurate and artificial, but which he made use of to determine the identity of animal species, viz. "any two animals that can procreate together, and whose issue can also procreate, are specifically the same." In this, however, it has been observed that he contradicts himself by afterwards admitting that the sheep and goat are of different species, at the same time that he asserts that the he-goat and the ewe produce a mixed breed which continue fertile for ever. Dr John Hunter (a great authority) was also of opinion that the true distinction between different species of animals must ultimately be gathered from their incapacity of propagating with each other an offspring capable of again continuing the kind. Thus the horse and ass beget a mule capable of copulation, but incapable of begetting or producing offspring. The accident of a mule breeding, according to the same authority, even if it were proved, would only show that as many perfect animals of true species and distinct sexes are incapable of breeding at all,—(thus showing that nature, even in her greatest perfection, sometimes deviates from general principles),—so it may occasionally happen that a mule shall breed from the circumstance of its being "a monster respecting mules."

The doctrine of equivocal generation has received no support from any recent investigations. All that is *known* decidedly leads to the opposite conclusion; and if certain mysterious or unaccountable phenomena have perplexed the physiologist, the only legitimate deduction is, that he has met with something which he cannot comprehend; for those aberrations (if such they really are) from the usual laws of nature are not so much exceptions to the general rule, as additional instances of effects in nature, the regulating causes of which we are as yet incapable of demonstrating. The rules of philosophizing lead us to reject the admission of more causes than are sufficient for the explanation of phenomena; and if, for example, mites, and "such small deer," derived their origin solely from the caseous and other substances in which they are generally found, the sexual distinctions which prevail among other animals would in them be unnecessary, and would not therefore be observable. But we know that distinct sexes do exist among these minute creatures—that they propagate their kinds after the accustomed mode—and we hence fairly infer that fortuitous generation does not take place among them. May we not therefore conclude that the origin of those first observed is similar to that of the thousands which we afterwards *see produced* according to the usual process? Nature does nothing in vain, and it is not consonant with her usual practice to suppose that she would authorize two distinct modes of creation in the same animal, where one of these is evidently perfect and self-sufficing. It may therefore be laid down as a general rule, that all living beings proceed from others of a similar nature, either by generation, offset, or some other means; and that, in all instances of apparently spontaneous production, there has existed some minute or imperceptible germs, which deceive us by their sudden development when placed under favourable circumstances. "In fact," says Cuvier, "however feeble and minute the parts of an embryo or the seed of a plant may be at the moment we are first capable of perceiving them, they then enjoy a real life, and possess the germ of all the phenomena which that life may afterwards develope. These observations, extended to all the classes of living bodies, lead to this general fact, that there are none of those bodies which have not heretofore formed part of a body similar to itself, from which it has been detached." "It is from them (their parents) they have received the vital impulse; and hence it is evident that, in the actual state of things, life proceeds only from life, and that there exists no other, except that which has been transmitted from one living body to another by an uninterrupted succession." "Origin by generation, growth by nutrition, termination by death, are the general and common characteristics of all organized beings.[1]"

At the same time it must be admitted, that the origin of many infusory and intestinal animals is sufficiently obscure. Of the latter class, one of the most extraordinary is a monstrous worm, as it may be called, which at distant intervals, and in parts of the world far removed from each other, has been found to inhabit the liver of the human race. The means by which it is bred, or the circumstances favourable to its production, are quite unknown; and some of the most philosophical inquirers of the present day have been unable to account for its origin, otherwise than by supposing that the viscus called the liver becomes, under certain circumstances, endowed with the power of actually secreting a substance capable of assuming and presenting the phenomena of distinct animal existence, and which, prior to the period of its being observed, had in fact become a specific animal;—at least its existence, unlike that of mites, flies, &c. which so often misled the ancient naturalists (though "*in* limo non *ex* limo" is Ovid's more accurate expression), cannot be accounted for in any other way. "There are," Mr W. S. Macleay observes, in his excellent and ingenious *Horæ Entomologicæ*, "many circumstances which might be adduced to support the belief that, whether from disease or other causes, there are periods when other parts of a body besides the ovarium may produce living germs, and demonstrate thus the polype nature of the cellular substance."

A polypus has been sometimes described as an animalized tube, capable of digestion, and possessed of a certain power of motion and reproduction; and these few words may be said to contain almost all that we know of its essential nature and attributes. As we advance in the scale of creation, we find a more complicated system of organs, with more varied powers of action, and a higher development of those accommodating instincts which, though circumscribed within certain impassable boundaries, yet seem at times to form such an approach to reason, as to connect the unvarying mechanical actions of the most simple zoophytical tribes with the conscious self-regulating power which has its final and most perfect development in the human race. The excellence of man, however, physically considered, consists more in the balance of various powers than in any one bodily superiority; for there is in fact no single sense in which he is not excelled by one or other of the brute creation. Materialists, who regard the intellectual superiority of man as the result of his physical structure, must also, for the sake of consistency, maintain his excellence as a machine to be infinitely be-

[1] *Lectures on Comp. Anat.* vol. i.

fore that of every other animal. But as his indubitable superiority depends on something totally immaterial, which "throws him out of the group of animals, and makes him an insulated being," there is the less necessity for either naturalists or metaphysical inquirers endeavouring to demonstrate the superexcellence of his physical condition. Man is in all cases "wonderfully," and in many cases "fearfully made;" but in the powers of sight, touch, hearing, and smell, he is greatly surpassed by many animals; and even in the sense of taste, in which his practice is more varied and extensive, he is at least equalled by the great majority. It is indeed somewhat remarkable that the last-named sense, the only one in regard to which the human race can lay claim to the possession of equal excellence with the brutes that perish, should be the grossest and least intellectual of the whole.

Although it is by no means strictly true that the brain, considered in relation to the size of the body, decreases as we descend from man to the lower tribes, because in many small birds, such as sparrows and finches, the brain is relatively much larger than in the human race, yet, exclusive of some such exceptions, it may be asserted that that important organ becomes less as we descend from mammiferous animals and birds, to reptiles, fishes, and other lower forms. Yet no very accurate conclusion can be deduced regarding the degrees of intelligence in different animals, from the proportion which the quantity of brain bears to the mass of the whole body, particularly when we come to compare animals of the same class with each other. It is in fact by no means easy to ascertain with accuracy what that proportion really is, because the weight of the brain is supposed to remain the same, while that of the animal varies according to its temporary condition. In this way only can we account for the contradictions which appear in the tabular views which have been given of these proportions by physiologists. Upon the whole, the smaller animals pertaining to the higher classes appear to have proportionally the largest brain, though man is in this respect seldom surpassed. The proportional weight of the brain to the body of man varies from 1-22d to 1-35th part, that of the gibbon or long-armed ape is as 1 to 40, that of the young malbrouk (*Simia Faunus*) as 1 to 24, that of the fox as 1 to 205, that of the beaver as 1 to 290, that of the field-mouse as 1 to 31, that of the elephant as 1 to 500, that of the horse as 1 to 400, that of the eagle as 1 to 160, that of the sparrow as 1 to 25, that of the canary-bird as 1 to 14, that of the cock as 1 to 25, that of the goose as 1 to 360, that of the land-tortoise as 1 to 2240, and that of the sea-tortoise as 1 to 5688.

Soemmering, Ebell, Vicq-d'Azir, Gall, and Tiedemann, supposed that every thing depended on the *volume* of the brain. But as Buffon and Daubenton had proved that the Sapajous have the brain proportionally larger than man, without surpassing their congeners in intelligence, it has been maintained by others that the volume alone was not a condition of superiority. Now the Sapajous in question have no *convolutions* to the brain, so that the surface of that organ is represented by that of the interior of the cranium, and exceeds it in other cases in proportion as its folds are numerous and profound; and as there appears to be a constant relation among mammiferous animals between the diminution of the cerebral surfaces and their intellectual degradation, whilst no such relation can be traced between the degrees of degradation and the variations of the brain in respect to size, it has hence been inferred by some that the extent of surface, and not the volume of the brain, ought to be regarded as co-relative with the intellectual faculties.[1]

In proportion, however, as the superior portion called the brain decreases in size, the medullary matter appears to collect in other parts of the body, or in the cords which emanate from the brain; so that many animals with much smaller brains have nerves more voluminous in proportion to their bodies than those of man. This medullary substance, the medium of sensation, is, in the human race especially, collected into one principal mass as the engine of thought and reflection, the intellectual attributes by which man is characterized; but it becomes dispersed in the inferior animals, or ramified over the whole body in the form of ganglions or nervous chords, without any preponderating superior brain. It is owing to this dispersion of the nervous system into these small separate centres in the polypus and other tribes, that almost every portion of the body, when separated from the rest, is capable of becoming a distinct animal, and of assuming an independent existence. In the lowest tribes of all, in which the nervous system has not yet been demonstrated, it probably consists of molecules of inconceivable minuteness, disseminated through the pulpy or gelatinous masses of which the bodies of many radiated and infusory animals are composed.

Singular effects result from the dispersion of the brain into so many small and separate centres; and this class of phenomena also illustrates the analogy which exists between the lower animals and the vegetable world. Among the superior creatures no reproduction takes place except of the fluids, and of whatever partakes of the nature of the epidermis. Injury is repaired and superficial parts renewed, but nothing resembling regeneration of important organs ever takes place. But it is otherwise with the inferior orders. The tentacula of the polypus and of many molluscous animals, the rays of the star-fish, the external members of the salamander, and the entire head, with the eyes and antennæ of the snail, when cut off, are speedily renewed. There are also animals, such as the planaria, which reproduce by offsets after the manner of plants; and a polypus may be divided into many portions, each of which becomes perfect according to its kind;—thus in a manner realizing what the ancient poets have feigned regarding the hydra of the Lernean marshes.

If the head of a mammiferous quadruped, or of a bird, is cut off, the consequences are of course fatal. But the most dreadful wounds that imagination can figure or cruelty inflict have scarcely any destructive influence on the vital functions of many of the inferior creatures. Riboud stuck different beetles through with pins, and cut and lacerated others in the severest manner, without greatly accelerating death. Leeuwenhoeck had a mite which lived eleven weeks transfixed on a point for microscopical investigation. Vaillant caught a locust at the Cape of Good Hope, and after excavating the intestines, he filled the abdomen with cotton, and stuck a stout pin through the thorax, yet the feet and antennæ were in full play after the lapse of five months. In the beginning of November, Redi opened the scull of a land-tortoise, and removed the entire brain. A fleshy integument was observed to form over the opening, and the animal lived for six months. Spallanzani cut the heart out of three newts, which immediately took to flight, leapt, swam, and executed their usual functions for 48 hours. M. Virey informs us, "Nous avons vu une salamandre vivant depuis deux mois, quoique décapitée au moyen d'une ligature serrée du cou." A decapitated beetle will advance over a table, and recognise

[1] See Desmoulins, *Rech. Anat. et Phys.*, and the *Journ. Compt. du Dict. des Sciences Med.* Septembre 1822.

a precipice on approaching the edge. Redi cut off the head of a tortoise, which survived 18 days. Colonel Pringle decapitated several libellulæ or dragonflies, one of which afterwards lived for four months, and another for six; and, which seems rather odd, he could never keep alive those with their heads on above a few days.[1]

Some curious particulars connected with the great tenacity of life in the lower animals are mentioned by Mr Fothergill.[2] A friend being employed one day in the pursuit of insects, caught a large yellow dragonfly (*Libellula varia*), and had actually fastened it down in his insect box, by thrusting a pin through the thorax, before he perceived that the voracious creature held a small fly, which still struggled for liberty, in its jaws. The dragonfly continued devouring its victim with great deliberation, and without expressing either pain or constraint, and seemed totally unconscious of being pinned down to the cork, till its prey was devoured, after which it made several desperate efforts to regain its liberty. A common flesh-fly was then presented to it, when it immediately became quiet, and ate the fly with greediness: when its repast was over it renewed its efforts to escape. This fact being mentioned to Mr Haworth, the well-known English entomologist, he confirmed the truth of the remarkable insensibility to pain manifested by insects, by narrating an additional circumstance. Being in a garden with a friend who firmly believed in the delicate susceptibility of these creatures, he struck down a large dragonfly, and in so doing unfortunately severed its long abdomen from the rest of the body. He caught a small fly, which he presented to the mutilated insect, by which it was instantly seized and devoured; and a second was treated in the same manner. Mr Haworth then contrived to form a false abdomen, by means of a slender portion of a geranium; and after this operation was performed the dragonfly devoured another small insect as greedily as before. When set at liberty, it flew away with as much apparent glee as if it had received no injury. It is a fact well known to practical entomologists, that large moths found asleep during the daytime may be pinned to the trunks of trees without their appearing to suffer such a degree of pain as even to awake them. It is only on the approach of the evening twilight that they seek to free themselves from what they must no doubt regard as an inconvenient situation.

The cruelty of zoological, especially of entomological pursuits, has too often been stated as an objection to the practical parts of the study of natural history. When a noble aristocrat (who thinks it sport to shoot a shepherd's dog) slaughters 100 brace of grouse in a single day, we hear nothing of such an objection, possibly because the flavour of moor-game is very exquisite; and the reason of defence is good. But the tastes of men differ, and fortunately, as all have not the means of an equal gratification from the same source. "Cruelty," say Messrs Kirby and Spence, "is an unnecessary infliction of suffering, when a person is fond of torturing or destroying God's creatures from mere wantonness, with no useful end in view; or when, if their death be useful and lawful, he has recourse to circuitous modes of killing them, where direct ones would answer equally well. This is cruelty, and this with you we abominate; but not the infliction of death when a just occasion calls for it. They who see no cruelty in the sports of the field, as they are called, can never, of course, consistently allege such a charge against the entomologist; the tortures of wounded birds, of fish that swallow the hook and break the line, or of the hunted hare, being beyond comparison greater than those of insects destroyed in the usual mode. With respect to utility, the sportsman, who, though he adds indeed to the general stock of food, makes amusement his primary object, must surely yield the palm to the entomologist, who adds to the general stock of mental food, often supplies hints for useful improvement in the arts and sciences, and the objects of whose pursuit, unlike that of the former, are preserved, and may be applied to use for many years. But in the view of those even who think inhumanity chargeable upon the sportsman, it will be easy to place considerations which may secure the entomologist from such reproof. It is well known, that in proportion as we descend in the scale of being, the sensibility of the objects that constitute it diminishes. The tortoise walks about after losing its head; and the polypus, so far from being injured by the application of the knife, thereby acquires an extension of existence. Insensibility almost equally great may be found in the insect world. This, indeed, might be inferred *a priori*, since providence seems to have been more prodigal of insect life than of that of any other order of creatures, animalcula perhaps alone excepted. No part of the creation is exposed to the attack of so many enemies, or subject to so many disasters; so that the few individuals of each kind which enrich the valued museum of the entomologist, many of which are dearer to him than gold or gems, are snatched from the ravenous maw of some bird or fish, or rapacious insect, would have been driven by the winds into the waters and drowned, or trodden under foot by man or beasts; for it is not easy in some parts of the year to set foot to the ground without crushing these minute animals; and thus also, instead of being buried in oblivion, they have a kind of immortality conferred upon them. Can it be believed that the beneficent Creator, whose tender mercies are over all his works, would expose these helpless beings to such innumerable enemies and injuries, were they endued with the same sense of pain and irritability of nerve with the higher orders of animals?"[3] Instead, therefore, of believing, and being grieved by the belief, that the insect we tread upon,

> In corporal sufferance finds a pang as great
> As when a giant dies,

the very converse is nearer the truth. "Had a giant lost an arm or a leg," continue the authors just quoted, "or were a sword or spear run through his body, he would feel no great inclination for running about, dancing, or eating. Yet a tipula will leave half its legs in the hands of an unlucky boy who has endeavoured to catch it, and will fly here and there with as much agility and unconcern as if nothing had happened to it; and an insect impaled upon a pin will often devour its prey with as much avidity as when at liberty. Were a giant eviscerated, his body divided in the middle, or his head cut off, it would be all over with him; he would move no more; he would be dead to the calls of hunger, or the emotions of fear, anger, or love. Not so our insects: I have seen the common cockchafer walk about with apparent indifference after some bird had nearly emptied its body of its viscera; a humble bee will eat honey with greediness though deprived of its abdomen; and I myself lately saw an ant, which had been brought out of the nest by its comrades, walk when deprived of its head. The head of a wasp will attempt to bite after it is separated from the rest of the body; and the abdomen, under similar circumstances, if the finger be moved to it, will attempt to sting." Query, which part felt conscious of being the original wasp?

That the acuteness of bodily suffering, even among the

[2] *Essay on Natural History.*

[3] Introduction to *Entomology*, vol. i. p. 56.

higher classes of the brute creation, is in some manner providentially subdued, and rendered so much less acute as not to be a fit subject of comparison with the suffering of the human race, is indeed evident from various phenomena, whatever the cause may be. The writer of this article has seen a turtle-dove (*Columba risoria*) which was so severely lacerated by a cat, that the contents of its stomach were torn out. The painfully excited sympathy of those who had long cherished the gentle creature was, however, in a great measure allayed by seeing the bird immediately afterwards proceed to pick up the fresh grains of barley which (till the aid of the surgeon was called in) continued to fall from its wounded paunch.

Considerations of the nature glanced at in the preceding paragraphs can never, of course, be so misconstrued as to afford any palliation to wanton or inconsiderate cruelty to the brute creation. The judges of the Areopagus who condemned to death the child whose amusement it had been to pluck out the eyes of quails, were regulated in their determination by the motives imputed to the young criminal, and which they deemed expressive of so cruel and pernicious a character, that in after-times he would assuredly offend the state. "Nec mihi videntur Areopagitæ," says Quintilian, "cum damnaverunt puerum coturnicum oculos eruentem, aliud judicasse, quam id signum esse perniciosissimæ mentis, multisque malo futuræ, si adolevisset."[1] But had some great oculist, intent on the structure and physiology of the human eye, and engaged in a difficult course of experimental observation, by means of which the "dim suffusion" which often veils the orbs of his fellow-men might be obviated or decreased, found himself under the necessity of having recourse to a somewhat similar operation, the case would have assumed another character, and the most sentimental philanthropist must have applauded the practice of the philosopher. So it is in a great measure with the pursuits of the naturalist. If the wonderful structure of the lower orders of creation cannot be studied or understood, or their infinitely varied forms held in remembrance, without hastening by a few days or hours the termination of that brief career which in truth scarcely ever meets with a strictly natural end, then is the student of nature, following out the principles of an elevating and intellectual pursuit, as well entitled to command a portion of animal life as he who, to pamper the refined grossness of a sensual appetite, bleeds his turkeys to death by cutting the roots of their tongues, boils crabs and lobsters alive, and swallows unsuspecting oysters by the score.

The more perfect the nervous system, the greater is the degree of intelligence. Indeed, were it not that no trace of that system has yet been discovered in many zoophytes, we might almost assert that the presence of nerves constitutes animal life, and that their absence in organized matter reduces it to the vegetable state. The greater the extent of brain in proportion to the size of the body, the greater in general the degree of sensibility. A French anatomist, in dissecting a horse of which he had admired the noble qualities, exclaimed, "J'ai long temps douté si nous avions le droit de monter sur ton dos ; mais en voyant la petite capacité de ton cerveau, je n'en doute plus maintenant ; tu n'est qu'une bête." The most perfect animals are such as are provided with a head which serves as the centre of their sentiments and sensations, and with a mouth for the reception of their nourishment. Their forms are symmetrical, or composed of two equal parts ; they change their place by a voluntary act ; their sexes are distinct, and separately incapable of continuing the species ; they are provided with five senses, and endowed with the perception of pleasure and of pain. The inferior tribes, on the contrary, which present so many analogies to the vegetable kingdom, have no distinct head, or single organ of life ; they are not symmetrical or composed exactly of two equal parts, but rather affect the circular or radiated form ; and for the most part they either remain fixed to the place which gave them birth, or with difficulty change their places of abode. The sexes are frequently united in the same individual, and their senses are limited to such as are necessary to a very confined and almost vegetative existence.

Though no animal has more than five senses, a great many are much more sparingly endowed. The only universal sense seems that of touch. The next to be developed is probably that of taste, then sight, hearing, and, lastly, smell. In the human race the senses are more equally balanced than in the brute creation, among the different tribes of which we find many animals as remarkable for their extreme acuteness in certain senses, as for their obtuseness in respect to others. The sense of smell in the dog, excepting some artificial varieties, such as the greyhound, prevails over every other ; birds of prey are remarkable for their keenness of sight ; the sense of hearing is strong in the hare ; that of touch in the trunk of the elephant ; that of taste in the lord of the creation. It follows as a consequence that the dog is by nature a hunting animal ; that the eagle, upborne upon resplendent wing, describes its magnificent circles in the air, "sagacious of its quarry from afar ;" that the hare couches securely among the long dewy grass, with its head so low that its eyes must be almost useless, but trusting to its quicker ears, which warn it of an approaching foe ; that the elephant examines the exact nature of all objects by touching them with the fleshy finger of its proboscis ; and that Mrs Rundell's work on cookery has run through countless editions. All insects in the perfect state, and the greater proportion of their larvæ, a part only of the molluscous tribes (such as the inhabitants of univalve shells), crustaceous animals, such as crabs and lobsters, and all fishes, reptiles, birds, and quadrupeds, enjoy the sense of sight ; and all these classes (with the exception of insects and many of the mollusca) are also furnished with the organs of hearing. That the latter sense, however, also exists in insects, may be fairly inferred from the frequent and varied sounds which they are capable of producing, although the seat of the faculty has not yet been ascertained. Many zoophytical tribes, which have no special organs of sight, appear to become sensible to the presence and action of light, through a delicate perception of the sense of touch. According to Buffon, the sense which has the strongest affinity to thought is that of touch ; and he regards it as being enjoyed by man in greater perfection than by animals. That which has the strongest affinity to instinct and appetite is smell,—a sense in which man must acknowledge an infinite inferiority. Hence, according to the Frenchman, man has the greatest tendency to knowledge, and the brute to appetite. There is no doubt that in man and the different species of monkeys the sense of touch is highly discriminating ; but it is assuredly a false view of the subject which has led Helvetius and others to attach such an extraordinary degree of importance to the *hand*, as the medium of intellectual superiority in the human race.

Whatever exhibits the phenomena of either animal or

[1] *De Inst. Orat.* lib. v. cap. ix. *de Signis.*

vegetable life, advances towards the perfect development of its parts through the medium of aliment. This name is applied to the numerous and diversified substances which, when introduced into the system of an organized body, have the power of identifying themselves in part with that system, in such a manner as to effect its nourishment, reparation, and increase. "Nourishment," says Bacon, "ought to bee of an inferior nature and more simple substance than the thing nourished. Plants are nourished with the earth and water, living creatures with plants, man with living creatures. There are also certain creatures feeding upon flesh; and man himself takes plants into a part of his nourishment: but man and creatures feeding upon flesh are scarcely nourished with plants alone. Perhaps fruits or graines, baked or boyled, may with long use nourish them, but leaves of plants or herbs will not doe it; as the order of the *Foliatanes* showed by experience living creatures are nourished by the mouth; plants by the root; young ones in the womb by the navill; birds for a while are nourished with the yolke in the egge, whereof some is found in their crops after they are hatched. All nourishment moveth from the centre to the circumference, or from the inward to the outward: yet it is to be noted, that in trees and plants the nourishment passeth rather by the barke and outward parts than by the pith and inward parts; for if the barke be pilled off, though but for a small bredth round, they live no more: and the blood in the veines of living creatures doth no lesse nourish the flesh beneath it than the flesh above it. Vegetables assimilate their nourishment simply without excerning; for gums and teares of trees are rather exuberances than excrements; and knots or knobs are nothing but diseases. But the substance of living creatures is more perceptible of the like; and therefore it is conjoyned with a kinde of disdaine, whereby it rejecteth the bad and assimilateth the good. It is a strange thing of the *stalkes* of fruits, that all the nourishment which produceth sometimes such great fruits should be forced to passe thorow so narrow necks, for the fruit is never joyn'd to the stock without some stalkes. It is to be noted, that the seeds of living creatures will not be fruitful but when they are new; but the seeds of plants will be fruitful a long time after they are gathered; yet the slips or cions of trees will not grow unlesse they be grafted green, neither will the roots keepe long fresh unlesse they be covered with earth."[1]

Nutritive substances of course vary according to the nature of the bodies which consume or absorb them. Plants derive their chief nourishment from air and water, the former of which must contain carbonic acid gas, the latter the dissolved remains of animal or vegetable substances. It is, however, possible to produce vegetable growth from pure water, assisted by warmth and air. Vegetables, again, serve as food to the greater proportion of animals, and these in their turn are devoured by the carnivorous few. It is thus that the productions of nature are connected together in one great circle, and are reciprocally dependent on each other. Without water there could be neither plants nor herbivorous animals, and without herbivorous animals there could be no carnivorous ones; therefore, without water there could be no life. Inorganic matter furnishes the first and most simple materials of existence; organic bodies perish and become decomposed, and thus adding to the mass of inorganic matter which they had for a short period abandoned, they enter again as elements into the composition of other and more complex forms. Indeed, according to Mr W. S. Macleay, organized matter is nothing but a peculiar modification of brute matter acted upon by the vital principle; but this form of expression probably throws no new light upon the subject.

We may here present a remark not unworthy of attention regarding the nature of the flesh in the different classes of the animal kingdom. Considered as a viand, the flesh of animals becomes less substantially nourishing as we descend in the scale. For example, the flesh of a quadruped contains a greater quantity of nourishment in proportion to size and weight than that of a bird, while the latter exceeds in that respect both reptiles and fishes. Hence in catholic countries the latter are justly regarded as *meagre*, and form an exclusive food during the frequent days of abstinence by which it is sought to mortify the flesh. Shell-fish and crustacea, and *a fortiori* the zoophytical tribes, yield a still smaller proportion of nutritious matter. A revolting conclusion has been drawn from this alleged relation between the flesh of a highly organized animal and the power and excellence of its nutritive qualities; viz. that cannibalism, or the habit of anthropophagous nations, opens up to those unnatural tribes a pleasure connected with the indulgence of the sense of taste greatly surpassing what is enjoyed by those who confine their mastication to the brute creation; because, in accordance with the rule supposed, the organic perfection and highly animalized nature of man is productive of a higher degree of nutrition, and of a greater capability of direct assimilation, when the substance of which he is composed is used as food by his fellow-mortals. But the scale of alimentary substances may rather be said to commence with air and water, and to terminate with the herbivorous animals; for the flesh of carnivorous kinds is, with very few exceptions, of a nature inadequate to the healthy sustenance of life. It is of a quality too putrescent, and decomposes with too great rapidity, as if the organization of matter could make no further progress, but passing rapidly from one extreme to another, hastened to throw off even the semblance of life, to assume again the simplest elementary form. "Over-great affinity," says Bacon, "or consubstantiality of the nourishment to the thing nourished, proveth not well; for creatures feeding upon herbs touch no flesh; and of creatures feeding upon flesh few of them eat their owne kinde. As for men which are cannibals, they feed not ordinarily upon men's flesh, but reserve it as a dainty either to serve their revenge upon their enemies, or to satisfie their appetite at some times. So the ground is best sowne with seed growing elsewhere; and men do not use to graft or innoculate upon the same stocke."

Mineral bodies are still more unfit for the purposes of nutrition. They furnish both medicines and poisons in abundance, but never aliments. The difference between these objects may be shortly stated as follows: Aliments are substances alterable by the action of the organs which appropriate them; medicines act on the organs, of which they alter or modify the action; poisons attack and extinguish life itself. But according to the specific nature of different animals, and various other circumstances, the qualities of these agents are convertible, so that aliments become poisonous, and poisons alimentary. Thus opium, which among European nations is a medicine, and too frequently a poison, has become, according to the practice of several eastern nations, an alimentary substance. Aloes, which are simply medicinal for the human race, are a destructive poison to many carnivorous animals. On the other hand, according to Pallas, hedgehogs eat abundantly of cantharides without being in the slightest degree incommoded by them; and bees are known to feed

[1] *History, Naturall and Experimental, of Life and Death.* English translation, 1638.

upon and form their honey from the secretions of many pernicious and even poisonous plants. The caterpillar of a certain sphinx moth is highly delighted with the acrid and venomous fluid of a tithymalis.

The more that animals enjoy the qualities of youth, strength, and activity, the greater is the increase and development of their parts, and the greater the necessity for an abundant supply of food. Of many individuals exposed to an absolute abstinence of many days, the young are always the first to perish. Of this the history of war and shipwreck offers in all ages too many frightful examples. There are several instances on record of an almost total abstinence from food for an extraordinary length of time. Captain Bligh, of the Bounty, sailed nearly 4000 miles in an open boat, with occasionally a single small bird not many ounces in weight for the daily sustenance of 17 people; and it is even alleged, that 14 men and women of the Juno, having suffered shipwreck on the coast of Arracan, lived 23 days without any food. Two people first died of want on the fifth day. In the opinion of Rhedi, animals support want much longer than is generally believed. A civet cat lived 10 days without food, an antelope 20, and a very large wild cat also 20; an eagle survived 28 days, a badger one month, and several dogs 36 days. In the memoirs of the Academy of Sciences there is an account of a bitch, which having been accidentally shut up alone in a country-house, existed for 40 days without any other nourishment than the stuff on the wool of a mattress which she had torn to pieces. A crocodile will live two months without food, a scorpion three, a bear six, a chameleon eight, and a viper ten. Vaillant had a spider that lived nearly a year without food, and was so far from being weakened by abstinence, that it immediately killed another large spider, equally vigorous but not so hungry, which was put in along with it. John Hunter inclosed a toad between two stone flower-pots, and found it as lively as ever after 14 months. Land-tortoises have lived without food for 18 months; and Baker is known to have kept a beetle in a state of total abstinence for three years. It afterwards made its escape.[1] Dr Shaw gives an account of two serpents which lived in a bottle without any food for five years.

The necessity of aliment becomes less vividly felt during sleep, and certain other periods of prolonged repose. There are several animals which hybernate, or go into winter quarters for six months in the year, during which period many of them require no food, but are maintained solely by that excellence of bodily condition which they had acquired during a prior period of activity and good cheer. This leads us naturally to consider what is called the *hybernation* of animals.

Many creatures are so constituted that the activity of their functions is greatly impaired by a comparatively slight reduction of temperature. Naturalists and anatomists have alike sought in vain for either external or internal characters of general application, by which they might distinguish, *a priori*, the species subjected to this strange though well-ordered lethargy. They belong to various genera and tribes, many of which have few characters in common, as will be perceived when we name as well-known instances the dormouse, the hedgehog, and the bat. It influences both warm and cold-blooded animals. The former of these, at certain advanced periods of the autumn, according to the species, seek out places of repose, either in the earth, among old walls, in caverns, trunks of trees, or bushes; which retreats they usually line with dried herbs, grasses, leaves, or moss. The bat chooses caverns, churches, barns, and other situations where the temperature is milder than that of the open air; and, contrary to the usual practice, it suspends itself by the hooked claws of its hinder extremities. It is the practice of other hybernating animals to contract themselves into a ball, in such a manner as to expose the smallest possible surface to the action of the air. When discovered in their retreats they are generally thus rolled up, cold to the touch, their limbs stiffened, their eyes closed, their respiration slow, interrupted, sometimes even imperceptible, and their insensibility so great that they may be removed, rolled about, and otherwise maltreated, without showing any further signs of life.

It has been observed that the temperature of these animals gradually lowers itself as the season declines. Their respiration also becomes slower, their motions less lively, and their appetite diminishes; but sensation and the power of locomotion still continue. This intermediate state between the perfect performance of the vital functions and confirmed torpidity endures for several weeks; the degree of temperature at which different animals become entirely overpowered varying, of course, according to the species. The propensity has been observed, in the following well-known animals, to correspond to a scale of descending temperature, according to the following order:—1*st*, The bat; 2*dly*, the hedgehog; 3*dly*, the dormouse; 4*thly*, the marmot; 5*thly*, the hamster. Although many other animals are subject to the same law, it is only among those just enumerated that an exact comparison has been instituted.

A complete state of hybernation consists in the suspension of sensation and voluntary motion, in addition to a great decrease in the temperature of the body, and in the frequency of respiration. Its different degrees of intensity are well ascertained by the number of respirations in a given time, or, in its most perfect state, by the total suspension of all respiratory movements. The different species of the bat tribe are those of which the torpidity is the least profound; and the marmot probably experiences the greatest degree of vital suspension. The temperature of these animals during their lethargy depends in a great measure upon that of the external air, and is consequently variable. It is in general, however, superior to it by several degrees. It may descend to within a few degrees of the freezing point, but is not susceptible of reduction to that point, without producing either re-action of the vital functions or death. There is, therefore, contrary to the opinion of some of the older naturalists, a degree of external cold incompatible with the torpidity or existence of these animals. The species most easily rendered torpid, such as the bat, the hedgehog, the dormouse, the lerot, and the muscardine, cannot support a cold of 14° of Fahrenheit. A warmth of from 50° to 53° brings them again to life. Sundry mechanical means, such as different degrees of motion, serve to restore several of the last-named species without any increase of temperature; but to preserve them in a state of prolonged activity, a gentle warmth must be applied and continued.

It is evident, from these and other observations, that the sleep of mammiferous animals is not characterized by a uniform and constant duration. As it is dependent on the variations of the atmosphere, it will commence at an earlier, continue a longer, or be interrupted after a shorter period, according to the difference in the seasons of particular years, the skill which the animals may have exhibited in the choice of a protecting habitation, or the peculiar constitution of the species, or even of the individuals. The habit of storing up a supply of winter provisions also depends upon their greater or less degree of exposure to

[1] See the observations prefixed to the translation of *Spallanzani's Tracts*, before referred to.

the power of awakening influences. The hedgehog, for example, has been observed to form several separate magazines, to which it has recourse during the winter season; and the marks of its little feet have sometimes been traced on the surface of the surrounding snow.

The hybernation of the swallow is a point on which very dissimilar opinions have been promulgated. It now appears to be the prevailing belief that these birds migrate on the approach of winter to other and more genial climes, but that cases do occur in which such individuals as are prevented by circumstances from joining the "marshalled array," are enabled to survive the rigours of our northern winters by the power which their constitution possesses of assuming the torpid state; at least the occurrence of torpid swallows, however rare, is too well authenticated to be a matter of doubt.

It is said that the tanrec, a species of hedgehog found in Madagascar, becomes torpid for some months in the year. If this assertion is well founded, it affords the only known instance of torpidity in a mammiferous quadruped of a warm climate.

Many cold-blooded animals may be regarded as of the hybernating kind. Indeed the greater proportion of reptiles, insects, molluscous animals, &c. inhabiting cold countries, are very lethargic during the winter season, which they usually pass without food. They appear subject to the influence of this feeling even in warm climates; at least Humboldt describes certain reptiles in South America which pass a portion of the year buried in the earth, and which are only aroused by the occurrence of rainy weather or the excitement of violent means. "The manners of animals," says this enlightened observer, "vary in the same species, according to local circumstances difficult to investigate. We were shown a hut, or rather a kind of shed, in which our host of Calabozo, Don Miguel Cousin, had witnessed a very extraordinary scene. Sleeping with one of his friends on a bench covered with leather, Don Miguel was awakened early in the morning by violent shakes and a horrible noise. Clods of earth were thrown into the middle of the hut. Presently a young crocodile, two or three feet long, issued from under the bed, darted at a dog that lay on the threshold of the door, and, missing him in the impetuosity of his spring, ran toward the beach to attain the river. On examining the spot where the barbacon or bedstead was placed, the cause of this strange adventure was easily discovered. The ground was disturbed to a considerable depth. It was dried mud, that had covered the crocodile in that state of lethargy, or summer sleep, in which many of the species lie, during the absence of the rains, amid the llanos. The noise of men and horses, perhaps the smell of the dog, had awakened the crocodile. The hut being placed at the edge of the pool, and inundated during part of the year, the crocodile had no doubt entered, at the time of the inundation of the savannahs, by the same opening by which Mr Pozo saw it go out. The Indians often find enormous boas, which they call *uji*, or water-serpents, in the same lethargic state. To re-animate them, they must be irritated, or wetted with water."[1]

Upon the whole, naturalists seem to be of opinion that no species of animal is condemned to torpidity by any inherent property of its nature. It is a provisional faculty, dependent on external circumstances, and may be interrupted, postponed, or altogether prevented, by regulating the conditions under which the animal is placed.

The disposition of animals in relation to other individuals of the same species differs considerably. There are some which unite in couples and divide between them the cares of the family. This is usually the case among the various tribes of birds, and also among carnivorous quadrupeds; whilst the males of such as feed on vegetables, and which consequently find almost everywhere an abundant and easy nourishment, abandon to the mother the rearing and education of their young. It has also been observed, that among such birds as feed on living prey, the male is very assiduous in assisting his mate to procure a sufficient supply. But naturalists have erred in assigning the polygamous habit as a general characteristic of the gallinaceous kinds. The instinct to pair, or the habit of monogamy, is no doubt only bestowed on those species to which it is necessary for the rearing of their offspring, and differs considerably in the nature and permanence of the attachment, according to the position of the nest, *i. e.* whether it is built upon or above the surface of the ground. All birds which build on trees, as was long ago remarked by Lord Kames, are hatched blind, and almost without feathers, and consequently require the sedulous care of both parents. But the generality even of gallinaceous birds, which breed upon the ground, do likewise pair, though the hatching of the eggs is entirely confined to the female, who completes her task by leading the young to their proper food, which they are able immediately to pick up for themselves, being active and well feathered from their birth. The male, at the same time, continues to manifest a certain degree of paternal solicitude, by uttering the alarm-note on the approach of birds of prey, or other dangerous foes. Black game and wood-grouse, however, do not appear to pair at all; but in the spring a male bird assembles a certain number of females about him, which afterwards deposit their eggs, and rear their young altogether independent of the male parent. They are therefore polygamous in the proper acceptation of the term. Even among herbivorous quadrupeds pairing is rare, because the female can suckle her young while she herself is feeding; but the monogamous habit probably obtains among most carnivorous quadrupeds, and certainly among all carnivorous birds, because incubation leaves the female no sufficient time to hunt for food,[2] and because young birds cannot bear a long fast, and therefore require the assistance of both parents, while unable to provide for themselves. The association or fellowship of birds is either annual or for life; the former bond is the more usual, though eagles, crows, and several other species afford examples of a long-continued attachment.

Many birds assemble in autumn, winter, and early spring, into flocks, but as soon as the pairing season has commenced they again separate into pairs. Others again appear to be more gregarious during the breeding season than at any other period of the year, for example the gannet or soland-goose (*P. bassanus*); but this arises not so much from a love of fellowship with their kind, as from the accident of there being few places fitted for the purposes of nidification and the rearing of the young.

We have said that pairing is rare among such quadrupeds as feed on grass, because the female can feed herself at the same time that she is suckling her young. The roe-deer, however, among herbivorous quadrupeds, forms an exception to the general rule. On the other hand, there are several carnivorous quadrupeds which do not pair, but the young of which are left entirely dependent on the mother; that is to say, the latter is obliged both to capture her own food and to suckle her offspring.

Among gregarious quadrupeds which usually store up food for winter, pairing is probably necessary to prevent discord, and in this respect beavers are said to resemble those birds which place their nests upon the ground. As

[1] *Personal Narrative*, vol. iv. p. 380.

[2] See Kames's *Sketches*.

soon as the young are produced, the males abandon their stock of food to their mates, and live at large, but return frequently to visit them while they are suckling their young. Hedgehogs and most of the monkey kind pair. Seals are polygamous, and turtles leave their young to be hatched by the heated sand. Earwigs, spiders, bees, and woodlice (*onisci*), are amongst the few of the insect tribes which pay any attention either to their eggs or offspring. The young of the greater proportion of animals is produced in spring, when the supply of food is the most abundant, and when the long period which intervenes before the approach of winter enables them to acquire strength to support the rigours of that inclement season.

Though the period of gestation varies considerably in the different quadrupeds which feed on grass, yet the females are regularly delivered in spring, or early in summer, when the herbage is nutritive and abundant. The mare conceives in summer, carries 11 months, and brings forth in May. The same is nearly the case with the cow. The sheep and the goat are usually in season in November; they carry five months, and produce when grass has begun to spring. They love short, close herbage, upon which a horse or cow would barely thrive. The ass is in season about the beginning of summer, but she bears twelve months, and consequently brings forth likewise early in summer. Wolves and foxes copulate in December, but as they only bear five months, they bring forth in April, when the season has assumed a genial aspect, and animal food is as abundant as at any other season. If we were to guess what would probably be the rutting season of animals, we would say summer, especially in a northern country; and yet, to quadrupeds which carry their young only for four or five months, such economy would be injurious and improvident, as it would bring the time of delivery at an undue season, both for warmth and food.[1] There are a few exceptions to the above rule, which, however, in themselves, belong to an equally beautiful system of providential ordinances. Some gregarious and store-collecting animals, for example, bring forth in January, when their granary of provisions is still abundantly filled.

The season of pairing, or of production, among wild animals, usually takes place only once a year, and at a fixed period; but those which man has rendered domestic are observed to couple at all seasons. The species of warmer climates, when transported into colder regions, usually cease to pair, or at least their union is unproductive; and the same consequence generally follows a state of captivity. Among such species, however, as man has fairly reduced to a state of satisfied domestication, the individuals become much more prolific than in the wild state.

The season of love varies greatly among mammiferous animals. The greater proportion pair in spring and summer; but the wolf pairs in winter, the stag in autumn, and many domesticated animals at diversified periods throughout the year. Prolific union takes place among *varieties* of the same species; and it is by paying attention to these that the finer races of our domestic animals are maintained and continued. As the climate of northern countries causes several of our most valuable animals to degenerate (as it is called), it has been customary to obtain from time to time a male animal of a pure and noble race, which, when paired with an ordinary female, produces a breed scarcely inferior to the male parent; for it has been observed that, with few exceptions, the new produce assumes the characteristics of the father. Thus, in uniting a sheep of an ordinary kind with a ram of the Merino race, the first generation almost equals the father in beauty.

What is frequently called deterioration in animals is, more properly speaking, their natural assumption of those peculiar attributes which fit them for the inclemencies of climates uncongenial to their original nature. A Laplander is no more a deteriorated Asiatic of the Mongolian or Caucasian line, than a Georgian or Circassian is a highly refined Laplander; neither is the Shetland pony a deteriorated Arabian courser, any more than the steed of Araby is a thorough-bred shelty. Each has been enabled by a wise provision of nature to assimilate its character and constitution to the qualities of the climate in which it was destined to exist; and had it been incompetent to effect or undergo such assimilation, it would then indeed have deteriorated—that is to say, it would have died. If we admire the slim smooth elegance of the Italian greyhound, and regard the rough shaggy coat of the dog of Nova-Zembla as a deterioration, let us remember that that which is the beauty of the one would be the bane of the other; and what would then become of that forlorn agriculturist, whose business it is to drill the ice and to furrow the snow? The small stature and peculiar habits of the northern pony would have been as little fitted to sustain the fiery breath or the shifting sands of an eastern desert, as the graceful Arabian to withstand the cold and cloudy clime, and the rugged and precipitous mountains, of Lapland or Thule. Therefore, instead of being deteriorated, each ought rather to be said to exist in the best and most improved condition, according to the nature of its particular calling. Using the word, however, in its more usual acceptation, it may be stated that an animal seldom degenerates in its native country, but more frequently in those for the climate of which its constitution is not adapted. Each species appears to have a certain extent or circle of natural distribution, in the centre of which it not only most abounds, but also there shows itself in its finest and most characteristic proportions. As the places of its occurrence diverge from this centre of dominion, it becomes rarer, and exhibits a variation or considerable departure, at least in its external characters, from the primitive model. Thus the horses of Arabia and Barbary degenerate in Britain; and, to preserve the breed in purity, they must be frequently crossed by the original; but the Arabs themselves are very careful to prevent any mixture in the blood of their native and noble kinds, and would deem them deteriorated by such alliance.

In the tabular or abridged views of classification which we here present, it is our intention merely to exhibit the great primary divisions of the animal kingdom called *classes*. The secondary divisions into orders, and the further dismemberment of these into minor groups called families, genera, &c., will be illustrated when we come to treat of each class in particular under its proper head. Neither do we intend to trace the progress of classification from the earliest ages of scientific record; because, as the object of the naturalist is rather to ascertain the nature and relationship of things as they are, than as they were supposed to be, there is the less necessity for leaving our direct route, to trace either the origin or the progress of error. We shall proceed, after a few observations, at once to the system of Linnæus, which is in fact the basis of all that have succeeded, and without a knowledge of which it is impossible to understand either the merits or defects of more recent systems. Indeed, with the exception of the purely artificial classification of Klein, and the multiplied orders of Brisson and Vicq-d'Azir, all the systems which have appeared since the middle of last century are indebted more or less to the labours of the immortal Swede, and may be valued almost exactly in pro-

[1] Kames's *Sketches*.

portion to their share in the *lucidus ordo* of the Linnæan system. For example, the *Systema Regni Animalis* of Erxleben (1777) is nothing more than a revised edition of the *Systema Naturæ*, in which are engrafted, with no lack of skill, many additions both of species and genera; the whole being presented in a consecutive series, without the accustomed subdivision into the primary groups called *orders*. The *Prodromus Methodi Animalium* of Storr (1780) does not differ radically from the Linnæan system. The *Elenchus Animalium* of Bodaert (1787) is allied to it still more closely in every thing except its accuracy. Of Gmelin's work (1789) we need not speak, as it is a professed revisal (being the 13th) of the *Systema Naturæ*. And although no one will deny the merit of profound and original inquiry to the investigations of Blumenbach, most readily will those who are best acquainted with his labours admit, that in zoology he has wisely followed the footsteps of Linnæus. The six classes into which the German naturalist divides the animated creation, viz. *Mammalia*, *Aves*, *Amphibia*, *Pisces*, *Insecta*, and *Vermes*, correspond with those of the Linnæan arrangement, although their orders and genera are in some respects differently combined. His motto appears to have been *Multa fiunt eadem, sed aliter*. (Quintilian.)

The signal benefits conferred on natural history, in all its branches, by the learning and genius of Baron Cuvier, are known wherever the science has obtained a zealous and successful cultivator; and it cannot have escaped the notice of the critical observer, that after 30 years of profound and philosophical research into the mysteries of the animal kingdom, the most enlightened zoologist of the age should have finally reverted to a closer approximation to the Linnæan system, than had characterized his views at any former period of his brilliant career. When he first made known (in 1797), conjointly with M. Geoffroy, his new classification of mammiferous animals, his numerous genera were contained under no less than 14 different orders. Thirty years afterwards (in 1817) he published his *Règne Animal*, with many improvements in the composition and arrangement of the minor divisions, and with the addition of the order of which he is himself so bright an ornament, but otherwise composed (we speak at present of the mammalia alone) of primary divisions exactly the same in number, and nearly the same in nature, as those finally divulged and established by Linnæus himself just 60 years before.

Latreille, Dumeril, Desmarest, and Frederick Cuvier, are followers or coadjutors of the Baron, and with him are partakers in the modification and amendment of the Linnæan system. The venerable Lamarck has greatly signalized himself in a field which, it must be confessed, was obscure to the eye of Linnæus—that of the molluscous animals—which, under the name of Vermes Testacea, were but indifferently treated in the *Systema Naturæ*. The error appears to have lain in the greater attention which was bestowed on the shells themselves, or testaceous coverings, than on the animal inhabitants; and the consequence has been, that the conchologist of the old school ranks with the collector of china, whether old or new.

The names above enumerated are certainly among the foremost in the annals of modern science; and although, in addition to these, many more might be mentioned with honour as having contributed, by monographs or other partial though highly prized contributions, to the increase of knowledge, yet we are not aware that more than three systematists of acknowledged and wide-spread influence, or of what may be termed universal celebrity, remain unnoticed, of those who have essentially influenced the present condition of zoological science; we mean Fabricius, Illiger, and M. de Blainville. We have no hesitation in asserting, that as the writers first mentioned owe much of the success which has attended their labours to their having judiciously engrafted their own improvements on the original stock of the Linnæan system, so the authors last named, though not less highly gifted, have in a great measure sacrificed the utility of many original and enlightened views to the fond conceit of a new, and in some instances an incomprehensible, nomenclature.

The skill of Fabricius as an entomologist has never been surpassed, and it is therefore the more to be regretted that he should have been influenced in the formation of his system by other motives than a desire to perceive and point out the truth. But it is known that he was swayed as much by the ambitious hope of founding a new doctrine, of which he destined himself to be the oracle, as by the desire of proceeding directly in the path of nature. Hence his avowed enmity to the eclectic system of Latreille, which, during the opening career of that celebrated entomologist, he declared it to be his intention utterly to destroy. Yet the system of Latreille not only stands, but, when viewed in relation to the application of its general principles, has in a great measure superseded that of Fabricius. At the same time, the accurate discrimination and extensive knowledge of the latter, and the wide circle which his system embraces in detail, render it still indispensable for a knowledge of the species.

Illiger died young. His talents were such as to raise among his compatriots the highest hopes of his future eminence, and his death was a subject of just regret to all who knew what he had achieved so well at an early age, and who the more gladly lent themselves to the anticipation of what he would afterwards have accomplished had his life been prolonged. Of his classification it has been written by a competent judge: "Neque apud veterem, neque apud recentiorem quendam auctorem ullum systema invenerim, quod, tam sua perspicuitate, quam accuratione, Illigeriano magis commendari mihi videatur." Many of his genera are indeed remarkable for their felicitous construction and consonance with the natural arrangement. They have in consequence been readily adopted by his more fortunate fellow-labourers in the same field, in whose works they will remain, and be handed down in ample attestation of the author's genius; but the system itself will suffer a partition, and ere long cease to be practically known under the form in which it was originally promulgated, and this mainly in consequence of his having adopted so many new names.

M. de Blainville is still alive, and the longer he lives the better for the sciences of anatomy and physiology, neither of which contains in its modern annals the name of a more accomplished or enlightened expounder of its mysteries than his own; but in the character of a naturalist, and in connection with the subject of nomenclature, he unfortunately sins more than all his predecessors. He really miscalls the objects of zoology most sadly, yet his knowledge of the essential bases of the science is no doubt too profound to admit of his applying it without new and important results. Hence the pity that these should not at all times be stated in such terms as not only to amalgamate more closely with the kindred labours of his contemporaries, but to fall rather more clearly within the comprehension of ordinary minds.

As it is not our intention in the present rapid sketch to enter into the distribution of the animal kingdom beyond the greater divisions called classes, we shall not exhibit the systems of the two first-named authors further than to say, that the former attended almost exclusively to entomology, the latter chiefly to the mammalia and birds. When we come to the divisions of our subject under their separate heads, tabular views or more detailed ana-

lyses will be presented of the labours of these and other ingenious inquirers of the past and present times.

We have said that we regarded the system of Linnæus as the basis of all those by which it has been succeeded, and that without a knowledge of his classification it would be impossible to understand either the merits or defects of more recent systems. We shall therefore here present the classes into which the great Swedish naturalist divides the animal kingdom.

Division I.

A heart with two auricles and two ventricles; blood warm and red.

Class I.—Viviparous animals, or such as suckle their young; commonly called quadrupeds, but including also the cetacea or whales,	Mammalia.
Class II.—Oviparous animals, or birds.....	Aves.

Division II.

A heart with one auricle and one ventricle; blood cold and red.

Class III.—Animals breathing arbitrarily through lungs....................	Amphibia.
Class IV.—Fishes, or animals with gills...	Pisces.

Division III.

A heart with one ventricle, no auricle; blood cold and white.

Class V.—With antennæ; undergoing transformations. Insects.......	Insecta.
Class VI.—With tentacula, and undergoing no transformations. Worms,	Vermes.

It may be observed, that the deservedly popular system of Linnæus, though it does not profess to be a natural method of classification, actually is so in many of its parts; nor can it be denied that, on the whole, it usually brings together as many groups of natural genera as occur in most systems that have been promulgated, especially if we take into consideration the period at which it was composed, and the comparatively scanty materials within his reach. Linnæus was probably aware of the extreme difficulty, we might say at once of the utter impossibility, of a perfectly natural arrangement; for he confesses, in his *Philosophia Botanica*, his inability to define the great divisions called *orders*, on account of their being so connected with each other by various points of affinity, as to form a map rather than a linear series; and the observation may be applied with equal truth to the subjects of the animal kingdom. In regard to the excellence of his genera themselves, their consonance with nature is rendered still more evident, by the great proportion of those which Cuvier and Latreille have retained as leading generic divisions in their recent works,—certainly the most skilful approaches which have yet been made in the establishment of a natural system. It has been asserted, and we believe with truth, that such naturalists as are perpetually intent on the abstract theory of classification, rarely attain the highest excellence in the discrimination or definition of the species,—the only distinctions possibly which have a real foundation in nature, and upon an accurate and extensive knowledge of which alone their theoretical systems can be substantially and permanently built. At all events, it is admitted that Linnæus is a guide almost infallible, in as far as concerns his wonderful facility in discovering the minor natural groups. If he could have combined these as well as he has defined them, his possession of the sceptre would have been still undoubted.[1]

M. Virey, in the first edition (1803) of the *Nouveau Dictionnaire d'Histoire Naturelle*, divides the animal kingdom into three great tribes, in accordance with the nature and distribution of the nervous system. As he appears to have been among the first to attribute a due degree of importance to that system in the classification of animals, we shall here exhibit a view of his general arrangement.

Tribe Vertebrata.

Animals possessed of two nervous systems, the cerebro-spinal and the ganglionic......................	Heart with two ventricles and two auricles; blood warm, lungs cellular....................	Man and Mammalia. Birds.
	Heart with one ventricle and one auricle; blood cold.......................................	Reptiles and Fishes.

Tribe Invertebrata.

Animals possessed of a single nervous system surrounding the œsophagus, with ganglia and branches; the *sympathetic*................	A heart; branchiæ for respiration, mostly aquatic..	Mollusca. Cirrhipedes. Crustacea.
	No heart; some vessels; tracheæ for air or water..	Arachnides and Aptera. Insects, winged, hexapod. Annelides and Helminthides. Intestinal worms.

Tribe Zoophyta.

Nervous system composed of molecules more or less perceptible; no distinction of sexes............	Ascidia, inclosed in a tunic....................	Botrylli, &c.
	Radiated animals; composed of rays parting from a centre...	Echinodermata. Hydra and Polypus.
	United in Polypiers, or stony masses; coralligenous..	Corals and Ceratophytes. Madrepores and Sponges.
	Microscopical...	Infusory Animals.

The following summary will serve to illustrate M. Virey's views of the nature and characteristics of these three great divisions. We commence with the zoophytical tribe.

1*st*, *Zoophytes* are distinguished by an organic tissue of a very soft and pulpy nature, more or less diaphanous, and very contractile, though we cannot readily perceive its muscular fibres. Its fundamental character consists in the extreme division of its nervous molecules throughout the flesh of these animals. Except in the Echinodermata and some other radiated classes, we can scarcely assert the existence of a nervous system amongst them (on which account they are named *apathiques* by Lamarck). Each portion of the body having its nervous molecule and its par-

[1] *Horæ Entomologicæ*, part ii. p. 428.

ticular source of vitality, there is no common centre of sensation; thus division and generation are almost synonymous, and when individual parts are mutilated they are speedily reproduced. With these tribes the production of the species is in fact nothing more than a simple sprouting of a bud or offset, which separates itself from the maternal stalk. Zoophytical animals are of no sex, and thus resemble the agamous vegetables. The mouth is usually placed in the centre of the body, and is frequently surrounded by a species of unarticulated arms, radiating from a centre like the petals of many flowers. Several genera have only a single opening for the reception and rejection of the aliment. They have no viscera (excepting *cæca* in certain species); no heart, nor arterial nor venous vessels; no true circulation; no apparent organs of respiration. They are all aquatic, and water seems indeed the only fluid which pervades their economy. They may be called the cryptogamia of the animal kingdom. The sense of touch, and perhaps that of taste, seem the only ones enjoyed by these animals.

2dly, The *Invertebrata* present a greater complication of organs. Their principal character consists in a nervous system, extending itself, especially in the intestinal cavity, by numerous ramifications. In all the families of this great tribe, the nervous trunks surround the œsophagus, pass beneath the belly, and are furnished with many ganglions which supply branches to the different organs. That which is regarded as the brain in this tribe (named *sensible* by Lamarck) is nothing more than one or two ganglia situated above the œsophagus; but the particular distribution of the two nervous branches which spring from the collar of the gullet, and extend themselves over the body, gives rise to the divisions of *molluscous* and *articulated* animals established by Cuvier.

The last-named naturalist has observed, that in the mollusca the nervous system is composed of many ganglionic masses, dispersed throughout the organization, but connected by means of nervous filaments; and that the chief of these masses constitutes a kind of brain above the œsophagus. The mollusca have no skeleton; their muscles are attached to the skin, a soft contractile envelope, in which in many species are produced shells, or stony bodies of calcareous carbonate, formed by exudation or superimposed concretion. Besides the sense of touch, common to all animals, the mollusca are gifted with that of taste, and sometimes of sight; but the sense of hearing has not been remarked, except among the *Cephalopoda* or cuttle-fish. Their systems of digestion and secretion are rather complex; they are provided with a liver, and possess a circulating or vascular system, through which flows a humour or whitish sanies in place of blood. Their respiration is effected by aquatic or aerial branchiæ. The sexual organs are frequently united in the same individual.

Among the articulated classes (such as the crustacea, the arachnides, and insects) the nervous system consists of a double chord, extending from the head to the posterior extremity, and bearing knots or ganglia which correspond to the segments of the animal's body. The first ganglion above the œsophagus takes the place of what we call the brain in the higher animals, but it is not voluminous in proportion. All these animals are composed of segments or annular divisions, and their forms are elongated, and more or less cylindrical. Their skin or outer covering, always of a somewhat solid texture, becomes in many families hard, corneous, or even stony; and the muscles are attached to its interior. The greater number have articulated members, feet, wings, pincers, palpi, &c. Many of these animals have closed vessels; and the crustacea have a heart and branchiæ. Others, according to Cuvier, are nourished by simple imbibition. Those insects which undergo metamorphoses are furnished with tracheæ or air-vessels for respiration, dispersed over their bodies. The organs of the sense of hearing are not discernible except among the crustacea; taste is universal, and also sight, except among the worms. Their jaws always ply laterally. The sexual organs are usually separate.

Animal Kingdom.

3dly, The *Vertebrata* comprehend all those animals which have a nervous system composed of ganglia, called sympathetic, for the functions of the internal life; and another symmetrical nervous system, of which the principal portions are inclosed in the cranium and spinal column, and which sends off chords for the functions of the external life. These are the most perfect and most highly endowed of all animals; they are named *intelligens* by Lamarck, and they are always endowed with five senses, of which never fewer than four are situated in the head. They possess a heart, red blood, a liver, lungs in the species which live in air, and branchiæ in those which live in water. An articulated, bony, symmetrical skeleton, placed in the interior of the body, gives support and solidity to the different parts. Such are man, mammiferous animals, and birds, which have warm blood, and respire by cellular lungs; such also are reptiles and fishes, of which the blood is cold. In all, the mouth has two horizontal jaws, and the members are never more than four in number.

The preceding are M. Virey's views of the distribution and general characteristics of the different classes of the animal kingdom.[1] They contain a sound exposition of several of the substantial relations which exist between the different systems of the animal economy, and we present them to the reader even at the risk of afterwards repeating in part several essentialities of his doctrine, when we come to promulgate the views of his celebrated countryman and contemporary Baron Cuvier.

We shall next present a tabular view of the general distribution and primary divisions of animals according to the system of Lamarck. It will be observed that this author commences with the lowest tribes.

Animals without Vertebræ.

* Apathetic Animals. (*Apathiques.*)

1. Infusoria. 2. Polypi. 3. Radiata. 4. Vermes.	*Characters.* No brain nor elongated medullary mass; no special senses, forms various; rarely articulated.

(*Epizoaria.*)

* * Sensitive Animals. (*Sensibles.*)

5. Insecta. 6. Arachnides. 7. Crustacea. 8. Annelides. 9. Cirrhipedes. 10. Mollusca.	*Characters.* No vertebral column; a brain, and generally an elongated medullary mass; some distinct or special senses; organs of movement attached beneath the skin; formed symmetrically of equal parts.

Animals with Vertebræ.

* * * Intelligent Animals. (*Intelligens.*)

11. Pisces. 12. Reptilia. 13. Aves. 14. Mammalia.	*Characters.* A vertebral column, a brain and spinal marrow; distinct senses; organs of movement attached to parts of an interior skeleton; formed symmetrically of equal parts.

[1] *Mœurs et Instinct des Animaux*, tome i. p. 180.

The author of the preceding arrangement has entered upon the discussion of certain preliminary points connected with the subject of classification, which may be regarded as composing the *art* rather than the *science* of Zoology. He inquires (in his introduction to the *Hist. Nat. des Anim. sans Vert.*) what are the operations to be performed for the execution of a good distribution of animals, and for the establishment of the necessary divisions of that distribution? These operations he states to be as follows: 1*st*, To assemble animals together according to a principle which is not arbitrary, and so as to form a general series, whether simple or ramified: 2*dly*, To divide this general series into different kinds of lesser divisions, of which the one shall be subordinate to the other; and with that view to make choice of and submit to certain suitable and convenient principles (*principes de convenance*): 3*dly*, To fix the rank of each sort of division after one general principle, previously established; as, for example,

The rank of each primary group in the total series;
That of the classical divisions of each primary group;
That of the orders or families in each class;
That of the genera in each family; and
That of the species in each genus.

The execution of these three sorts of operations is regarded by Lamarck as indispensable; and that it is so has been long felt by naturalists, almost all of whom have more or less occupied themselves in the attempt, but always in an arbitrary manner—that is to say, without the previous establishment of principles deserving of general consent. The first of the operations alluded to—that which concerns the bringing together of species in such a manner as to form a general series—is an essential preparation, which ought to precede the other operations, and without which indeed the latter could not be executed. It tends, moreover, to enable us to discover the order of nature, with which it is so highly important that we should become acquainted. Although nature has necessarily followed a certain order in the formation of organized beings, and especially of animals, yet as she has now dispersed these animals, and commingled all the different races over the surface of the solid globe, or through the wide depth of liquid waters, the original order of formation is to a certain extent disfigured, and so far imperceptible. We are therefore obliged, with a view to its ascertainment, to search after some means by which we may attain to that discovery, and to work out some solid principles to lessen the chance of error. In regard to this, the most important step has been already attained, when we acknowledge the interest inspired by affinities or relations, and the necessity of understanding these, with a view to submit to them, as to a test, the various parts of our general distribution. It may thus be perceived, that in order to establish a good distribution of animals, in such a manner that its solidity shall run no risk of being enfeebled by the arbitrary nature of opinion, it is necessary first of all to assemble our species according to well-determined affinities; after which we may, without inconvenience, trace out the lines of demarcation which separate the groups called classes, and those other subordinate groups of which the establishment is so advantageous, provided the natural relations are in nowise compromised by their formation. It may perhaps be proper shortly to inquire into the nature of these relations, their different degrees, and the exact uses which it becomes us to make of such as we ascertain and acknowledge. We shall then be enabled with greater facility to determine the principles which it is fit to establish.

Relations, according to Lamarck, are those traits of esemblance or analogy which nature has bestowed, as well on her different productions when compared among themselves, as on the different parts of those same productions when compared with each other. These traits of resemblance and affinity are so necessary to be known and understood, that no methodical distribution can be established on a sure foundation, if the objects which it embraces are not arranged according to the law which they prescribe. Relations are of different orders, some being very general, others less so, and many altogether special or particular. Moreover, although, in general, relations belong to nature, all are not the direct result of her operations in regard to her productions; for among the relations which we perceive between the compared parts of different beings, there are many which result merely from a modifying cause. Thus the relations of exterior form, which are so apparent between the cetacea and fishes, can only be attributed to a property resulting from the dense medium which each inhabits, and not to any direct plan in the operations of nature in regard to both It is necessary then carefully to distinguish those obvious and acknowledged relations which pertain to the direct operations of nature in the progressive organization of animal life, from certain others, equally obvious and acknowledged, which result from the influence of local circumstances, or from the peculiar habits which different races have in some instances been forced to acquire.

Relations of the last-named nature, though certainly of greatly inferior value to the former, are by no means limited in their influence and exhibition to external characters alone; for it may be demonstrated that the external cause which possesses the power to modify the direct operations of nature frequently exercises an obvious influence on several internal organs. It becomes the more necessary then to establish certain rules, devoid of arbitrary qualities, to enable us justly to appreciate the nature and value of these relations; and it may be established as a principle in zoology, that it is from the interior organization that the most essential are to be obtained. This principle is well founded if it expresses the pre-eminence which ought to be accorded to general considerations, gathered from the interior organization, over those derived from external parts. But if, instead of using it in this manner, we apply it to particular cases of our own choosing, and without pre-established rule, it is capable of great abuse; and we shall arbitrarily assign to relations presented by such or such system of internal organs, a preference over certain others, although the relations of the latter may in reality be of greater importance. By this means, sufficiently convenient for the changeable views of individual authors, we admit into various parts of our distribution inversions in every way contrary to the order of nature.

It is true, as has been already observed, that a cause which modifies organization not only acts on the exterior parts of animals, but also produces various modifications in their internal structure. It follows, that it is incorrect to suppose that the relations which exist between the races, and especially between the genera, the families, the orders, or even in certain cases the classes of animals, can always be decided merely from the isolated consideration of any internal organ, arbitrarily selected. On the contrary, Lamarck is of opinion that the relations of which we speak cannot be suitably determined except by a consideration and comparison of the whole of the interior organization, and, auxiliarly, by that of certain special internal organs which assured principles have demonstrated to be the most preferable and important.

The second question proposed by M. Lamarck is the following: What are the principles by which we ought to be guided in our operations, so as to exclude from these

whatever is arbitrary? Our author is of opinion that it is by the precise discrimination of each sort of relationship, and by aid of a determination, substantial and explained, of the preference which ought to be accorded to one kind over another, that we shall discover principles proper to regulate all the parts of our general distribution of animals. It is necessary then to determine the principal kinds of relations which ought to be employed to attain this end, and then to fix the superiority in value which one kind possesses over another. The following is the classification of Lamarck in further illustration of this subject.

* *Relations between Comparative Organizations, deduced from the whole of their parts.*

These relations, though general, manifest themselves in different degrees, according as we seek for them among races compared in themselves, or among groups of animals of different races compared with each other. It is necessary then to distinguish several kinds.

First kind of general relations.—These seem immediately to connect races or species with each other. They are of necessity the first, because it is they which furnish the greatest of the relations between animals which differ from each other. The *zoologist* who determines it, taking into consideration all the parts of organization, as well interior as exterior, admits not of this sort of relation, unless when it presents the smallest and least important difference. We know that animals which resemble each other perfectly, both in their internal and external organization, can be nothing more than individuals of the same species. In this case the relation is not considered, as such animals offer no distinction. But those which present among themselves a difference, tangible, constant, and at the same time the smallest possible, are connected by the greatest and most immediate of relations, if they present elsewhere a great resemblance in all the parts of their interior organization, as well as in the greater proportion of their external features. And this sort of relation does not demand a consideration of the degree of composition or relative perfection of the animal organization, for it determines itself in all the ranks of the scale. It is so easy to seize, that every one acknowledges it at first sight; and it is by employing it that naturalists have formed those smaller portions of the general series called genera, notwithstanding the arbitrary nature of their limits. Thus, in this first kind of relation, which may be called the *relation of species*, the difference between the objects compared is the smallest possible, and need only be sought for in the particularities of form or of the external parts of individuals.

Second kind of general relations.—This embraces the agreements which exist between groups of different animals when compared together. It may be named the *relation of groups;* and, to acquire a knowledge of its nature, we must no longer occupy ourselves essentially with the particulars of the general form, nor with those of the external parts, but almost solely with the interior organization, considered in all its parts. It is this kind chiefly which ought to furnish the differences by which we distinguish the groups from each other; and it is inferior in one or more degrees to the first kind in the quantity of resemblances which exist between the compared objects. It serves to form the *families*, by connecting the genera with each other; to institute the *orders*, or the *sections of the orders*, by uniting several families; and, lastly, it determines the classical groups into which we ought to partition the general series. The relations of which we now speak cannot, however, be employed to determine the *rank* of the great masses of that series, but only to form diverse combinations for establishing and distinguishing these masses.

From the consideration of these relations, the two following principles may be deduced.

First principle.—The general relations of the second kind do not require a perfect resemblance in the interior organization of the compared animals. "Ils exigent seulement que les masses rapprochées se ressemblent plus entr'elles, sous ce point de vue, qu'elles ne le pourraient avec aucune autre." (*Anim. sans Vert.* tome i. p. 355.)

Second principle.—The greater and more general the compared masses, the more will such masses differ in their internal structure. Thus the *families* present a less difference in the interior organization of the animals by which they are constituted, than the *orders* or *classes*.

Third kind of general relations.—We may denominate *relations of rank* those which serve to determine the position in the great series, and which, proceeding from a fixed point of comparison, effectively show among the compared objects a relation, whether great or small, in the composition or perfection of the organization. This kind is obtained by comparing any organization whatever, taken in the totality of its parts, with any other given organization which may be presented as a point of departure or of comparison. It is then determined, by the resemblance, greater or less, which is found between the two compared structures, to what extent that which we compare departs from or approaches to that which is given as a point of comparison. We shall see that this sort of relation is the only one which ought to serve for regulating the rank of all those important primary masses into which we divide the animal kingdom.

If we consider the question concerning the choice of a particular organization, from or towards which to remove or approximate other organizations successively, according to their greater or less resemblance, it becomes evident that the selection ought to fall on one or other extremity of the animal kingdom (as in that case there would be no uncertain balancing), and the best known extremity should have the preference. Thus, in setting out from the most perfect and highly finished structure, we should, in the determination of all the ranks, proceed from the most composite to the most simple, and should close the series by the most imperfect and least organized of the whole.

Of all forms of structure, that of man, considered in its totality, is at once the most composite and complete. From this M. Lamarck concludes that the more any animal organization approaches that of the human race, the more it advances towards comparative perfection and its own completion. This being the case, the organization of man is with that author the point of comparison and departure from which to judge of the relation, whether near or distant, of every form of animal structure, and by which we are to determine the rank which those forms, or the groups which they constitute, ought to occupy in the general series. The organization alluded to, considered in the totality of its parts, furnishes the means by which to judge of the degree of composition and perfection of other animal structures also regarded in their totality. And in doubtful cases it is not difficult to rid ourselves of uncertainty and embarrassment, by having recourse to the fourth kind of relations, or to those principles which concern the comparison of the different organs separately considered, and establish a predominating value and influence among certain of those organs when compared with others. Thus, our point of departure or comparison being found, the rank of all the divisions may be assigned with facility by the aid of the principles which follow.

First principle.—For the determination of the rank of each mass in the series,—the most complicated and complete of animal organizations being selected as the point of comparison,—the more another form of animal structure, considered in the whole of its parts, resembles that of the fore-chosen, the more it will approximate towards it by its relations; and reciprocally in the converse cases.

Second principle.—Among the organizations of which the plans are different from that which comprehends the particular structure selected as the point of comparison, those which offer one or more systems of organs similar or analogous to such as form a portion of that with which they are compared, shall rank superior to those possessed of a smaller number of these organs, and, *a fortiori*, to those in which they are wanting

With the assistance of the three kinds of relations above indicated, and the principles deducible from them, M. Lamarck regards it as easy to determine the distinctions of species, and those of the various larger groups which species form; and to decide, in a manner by no means arbitrary, the rank and station of each group in the great series. If this be true, the science will cease to be as vacillating in its onward march as it has hitherto proved.

But our efforts would be incomplete, and would still leave too large a field for the exercise of arbitrary opinions, if no attempt were made to establish and define the value of *particular relations*,—that is to say, of those which are obtained by the comparison of particular internal organs, considered in an isolated manner in different animals.

** *Relations between similar or analogous parts taken separately in the organization of different animals, and compared with each other.*

The *fourth kind of general relations* merely embraces particular relations between unmodified parts. It is drawn from the comparison of parts separately considered, and which, in the system of organization to which they belong, offer no real anomaly. The consideration of this kind is sometimes of great consequence in assisting to decide in doubtful cases, when we are anxious to determine, among certain compared groups, to which the superiority of rank ought to be assigned. Such cases sometimes occur where the whole of the parts of the interior organization present no means of deciding, in an unarbitrary manner, to which of two organizations the superiority belongs. It is especially in the formation and position of the orders, sections, families, and even genera, of each class, and consequently in the assignment of the rank of all these inferior groups, that the employment of this fourth kind of relations is of advantage; because, in regard to such groups, the principle of the third sort of relations is frequently very difficult of application; and thus arbitrary modes of arrangement are introduced, most baneful to the science, by exposing the works of naturalists to a continual variation in the determination of the relations which ought to fix the composition of the groups, and their order of position. In fact, as many animals, really connected by the general characters of their class, present remarkable differences in certain of their interior organs, and yet at the same time exhibit equally striking resemblances in others, we feel that, in order to appreciate the degree of importance possessed by the relations which exist between particular organs, we must have recourse to certain regulating principles in our determinations, to avoid arbitrary conclusions. The two following principles are proposed by Lamarck, to enable us to appreciate the relations observable between particular internal organs in different animals compared with each other.

First principle.—Between two internal organs, or systems of internal organs, separately considered and compared, that of which nature has made the most general employment ought to have the pre-eminence assigned it in the value of the relations which it presents. According to this principle, the following is the order of importance which we ought to attribute to the particular organs which nature has employed in the interior organization of animals:—

The organs of digestion;	The organs of production;
The organs of respiration;	The organs of sensation;
The organs of movement;	The organs of circulation.

Thus, when we take into view the greatest generality of employment of the particular organs of which nature makes use in the interior organization of animals, we perceive that the organs of digestion occupy the foremost rank,—those of circulation the last. We have thus an order of value or precedence, in regard to these important organs, capable of regulating, in doubtful cases, the preference which one relation merits over another.

Second principle.—Between two different modes of the same organ, or system of organs, that which is most analogous to the mode employed in a superior or more composite and complete organization, merits the preference in the relations which it exhibits. If, for example, we desire to employ a relation afforded by the organs of respiration,—to judge of the preference which it deserves over that offered by other organs,—we are obliged, according to the principle above established, to keep in view the following consideration:—Although the system of organs provided for respiration is very widely employed in the organization of animals, since, with the exception of the polyped and infusorial classes, all the rest possess a respiratory system, yet the mode of that system not being the same in all the classes by which it is exercised, we assign a higher value to the true *lung* than to the *branchia*, to the latter than to the *aeriferous tracheæ*, and to these than to the *aquiferous tracheæ*. According to this view, we may judge whether the mode of respiratory organs of which we wish to employ the relation, is sufficiently high in value to permit our yielding to it a preference over a relation deduced from some other kind of organs.

The *fifth kind of relations* embraces the *particular relations* observable between the modified parts. It requires that, among the parts compared, we should discriminate between that which is due to the real plan of nature, and that which pertains to the modifications which that plan has experienced from accidental causes. Thus this class of relations is derived from parts which, considered separately in different animals, are not in the state in which they ought to be, according to the plan of organization to which they belong. To judge of the degree of importance which ought to be accorded to a relation, and the preference which it deserves over another, it is a matter of no slight consequence to distinguish if the form, the increased or diminished development, or even the entire disappearance of the particular organs under consideration, belongs to the plan of organization of the animals subjected to such modifications; or whether the state of these organs is not rather produced by a modifying and determinable cause, which has altered or annihilated that which nature had executed, and would have maintained, but for the influence of that later cause. "For example," says Lamarck, "it would have been impossible for nature to furnish a head to the *infusoria*, the *polypi*, or the *radiata*, &c.; for the condition of these bodies, and the degree of their organization, did not permit it; and it was only on arriving at the class of insects that a genuine head could be supplied." Now, as nature never retrogrades in her operations, we naturally expect, that when once arrived at the formation of insects, and consequently of *heads*, the recipients of the special senses, all animal organizations

superior in composition to that of insects will also exhibit these organs. This, however, is not universally the case; because no distinct head is observable among the *annelides*, the *cirrhipedes*, and many *mollusca*, all of which are generally regarded as superior to the class of insects. "Une cause étrangère à la nature, en un mot, une cause modifiante et déterminable, s'est donc opposée à ce que les animaux cités soient pourvus d'une véritable tête." (*Anim. sans Vert.* tome i. p. 363.) And that cause appears to have operated sometimes by hindering to a greater or less extent the development of that part of the body, and at other times by effecting its complete destruction. We find the same thing in regard to eyes and teeth, and to various other parts both of the internal and external structure; because a modifying cause has had the power to alter, enlarge, diminish, or even to effect the total disappearance of these organs. We may perceive, then, that the relations obtained from the consideration of changed or modified parts must be of very inferior value to those furnished by the same parts existing in a state conformable to the plan of nature. Hence results the following

Principle.—Whatever nature has directly formed deserves a pre-eminence in value over that produced by a fortuitous cause, which has modified the work of nature; and in the choice of a relation to be employed, we should assign the preference to every organ, or system of organs, which we find existing as it ought to do according to the plan of organization of which it forms a part, over that organ, or that system of organs, of which either the condition or existence has resulted from a modifying cause, extraneous to original nature.

When two different organs, between which a choice is to be made, are both found to be changed or altered by a modifying cause, the preference should be given to that which is least removed by such a modification from the condition in which it would have existed according to the plan of organization of which it formed a part.

The *third question* proposed by M. Lamarck is as follows:—What disposition or mode of arrangement should be given to the general distribution of animals, so as to render it conformable to the order followed by nature in the production of these beings? To resolve this question, we must also endeavour to deduce some principle from nature herself, with a view to such conformity; for if we were to determine the general distribution of animals according to the progression which exists in the animal organization, it appears that we might, in that progression, proceed with as much reason from the most composite to the most simple, as from the most simple to the most composite. Such a proceeding, however, could not rest on a proper basis; for we shall find that nature, consulted in the order of her operations in regard to animals, indicates the following principle, which excludes all arbitrary selection:—*Nature always operating in a gradual manner, and consequently never producing animals otherwise than successively, has obviously proceeded in such a production from the most simple towards the most complex.* We ought, therefore, in our general distribution, to imitate the order which nature herself has followed. "J'ai, en effet, montré," says Lamarck, "dans ma *Philosophie Zoologique* (tome i. p. 269), que, pour rendre la distribution générale des animaux conforme à l'ordre qu'a suivi la nature en produisant toutes les races qui existent, il fallait procéder du plus simple vers le plus composé,—c'est-à-dire, qu'il était nécessaire de commencer cette distribution par les plus imparfaits des animaux, et les plus simples en organisation, afin de la terminer par les plus parfaits, par ceux qui ont l'organisation la plus composée." He further observes, in his *Anim. sans Vert.* "Cet ordre est le seul qui soit naturel, instructif pour nous, favorable à nos études de la nature; et qui puisse, en outre, nous faire connoître la marche de cette dernière, ses moyens, et les lois qui régissent ses opérations à leur égard." Although we may find it less pleasant or conformable to our habitual taste to present at the head of the animal kingdom creatures of the most limited perceptions, excessively minute in size, and of scarcely any consistence in their parts,—yet as in all things it is necessary to consider the end in view, and the means which conduct towards it, Lamarck is of opinion that the arrangement established by usage in the distribution of animals is precisely that which leads us away from the point in view, as well as the least favourable for our instruction, and that it opposes the greatest number of obstacles in the way of our perceiving the plan, the order, and the means employed by nature in her operations concerning the animal world.

If in the study and examination of living bodies we had no other object in view than to distinguish the one from the other by characters deduced from their external forms—and if we were not desirous to regard their various and wonderful faculties otherwise than as simple matters of amusement, not altogether unfitted to excite the curiosity of a leisure hour—then the most ordinary and artificial system would suffice; for in that case it would be useless to occupy ourselves with researches concerning the affinities of animals, or to study their internal structure. But all naturalists are now agreed regarding the high importance of these affinities, and the necessity of holding them ever in view in our general arrangement of the animal kingdom. The bat is no longer classed with birds merely because, like them, it wings its way through the air; nor are seals or whales regarded as fishes because the dense nature of the medium which they inhabit requires a somewhat analogous form; neither are cuttle-fish and polypi confounded together, though the mouth of each is surrounded by numerous arms.

We have dwelt at greater length than we intended on the system of Lamarck, or rather on the views by which he seeks to illustrate the principles on which his system professes to be built. Though occasionally prolix, and sometimes rather obscure, his observations, on the whole, are well deserving of an attentive consideration. Like most of his countrymen, he is unfortunately more regardful of secondary causes, and more anxious to illustrate their fitness and sufficiency, than he is ready to acknowledge the source from which they spring, or to admire the wisdom and beneficence of their providential institution.[1]

[1] "The doctrine of Epicurus, that the Deity concerns not himself with the affairs of the world or its inhabitants, which, as Cicero has judiciously observed (*De Nat. Deor.* lib. i. ad calcem), while it acknowledges a God in *words*, denies him in *reality*, has furnished the original stock upon which most of these bitter fruits of modern infidelity are grafted. Nature, in the eyes of a large proportion of the enemies of revelation, occupies the place, and does the work, of its great Author. Thus Hume, when he writes against miracles, appears to think that the Deity has delegated some or all of his powers to nature, and will not interfere with that trust (*Essays*, ii. 75); and, to name no more, Lamarck, treading in some measure in the steps of Robinet (who supposes that all the links of the animal kingdom, in which nature gradually ascends from low to high, were experiments in her progress towards her great and ultimate aim, the formation of man—Barclay *on Organization*, &c. 263), thus states his opinion:—"La nature, dans toutes ses opérations, ne pouvant procéder que graduellement, n'a pu produire tous les animaux à la fois; elle d'abord n'a formé que les plus simples; et passant de ceux-ci jusques aux plus composés, elle a établi successivement en eux différens systêmes d'organes particuliers, les a

Animal Kingdom.

We shall now proceed to the system of another naturalist, also highly accomplished in the science, M. Dumeril, the friend and pupil of Baron Cuvier, and to whose collection of the oral demonstrations of his great master we were originally indebted for the publication of the *Leçons d'Anatomie Comparée.*

Animal Kingdom.

Table of the Classification of Animals, according to the System of Dumeril.

Internally articulated; vertebrated;	with mammæ; viviparous			1. MAMMIFERÆ.
	without mammæ; oviparous;	lungs;	feathers, wings	2. BIRDS.
			neither feathers nor wings	3. REPTILES.
		no lungs; branchiæ		4. FISHES.
Externally articulated; invertebrated;	articulated members;	tracheæ		5. INSECTS.
		branchiæ		6. CRUSTACEA.
	no articulated members			7. WORMS.
Not articulated;	distinct respiratory organs; vessels			8. MOLLUSCA.
	no respiratory organs; no vessels			9. ZOOPHYTES.

The ensuing tabular view exhibits the classification proposed by M. de Blainville. We shall leave the reader to judge for himself of the propriety of introducing so many new appellations for groups constructed long ago. His nomenclature is no doubt intimately connected with his views of the structure and physiology of animals, and is highly approved of and adopted by many competent judges of the science.

SYNOPTICAL TABLE of the PRIMARY, SECONDARY, TERTIARY, and QUATERNARY DIVISIONS of the ANIMAL KINGDOM, denominated *Sub-Kingdoms, Types, Sub-Types,* and *Classes,* by M. de Blainville. From the *Principes d'Anatomie Comparée* of that author.

ANIMAL KINGDOM.

- *I. Sub-Kingdom.* Regular or ARTIOMORPHOUS Animals. ARTIOZOAIRES.
  - articulated
    - *Type I.* interiorly. OSTEOZOAIRES.
      - *I. Sub-Type.* Provided with mammæ and VIVIPAROUS. ...hairs — *Classes.* 1. PILIFERES or MAMMALIA.
      - *II. Sub-Type.* Without mammæ. OVIPAROUS. Provided with
        - feathers — 2. PENNIFERES or BIRDS.
        - scales — 3. SQUAMMIFERES or REPTILES.
        - naked skin — 4. NUDIPELLIFERES—AMPHIBIA.
        - fins — 5. PINNIFERES or FISHES.
    - *Type II.* exteriorly. ENTOMOZOAIRES, or articulated animals. With appendages,
      - articulated to the number of
        - 3 pair — 6. HEXAPODES.
        - 4 pair — 7. OCTOPODES.
        - 5 pair — 8. DECAPODES.
        - variable — 9. HETEROPODES.
        - 7 pair — 10. TETRADECAPODES.
        - = the segments — 11. MYRIAPODES.
      - not articulated — 12. CHITOPODES.
      - none — 13. APODES.
  - sub-articulated — *Type III.* MALENTOZOAIRES or MOLLUSCARTICULES
    - 14. NEMATOPODES.
    - 15. POLYPLAXIPHORES.
  - not articulated — *Type IV.* Malacozoaires. Molluscous animals. The head
    - distinct — 16. CEPHALOPHORES.
    - not distinct — 17. ACEPHALOPHORES.
- *II Sub-Kingdom.* Radiated or ACTINOMORPHOUS Animals. ACTINOZOAIRES.
  - sub-radiated — 18. ANNELIDAIRES.
  - normal or true
    - 19. CERATODERMAIRES.
    - 20. ARACHNODERMAIRES.
    - 21. ZOANTHAIRES.
    - 22. POLYPIAIRES.
    - 23. ZOOPHYTAIRES.
- *III. Sub-Kingdom.* Irregular or HETEROMORPHOUS Animals. HETEROZOAIRES
  - 24. SPONGIAIRES.
  - 25. MONADAIRES or MOLECULAIRES.
  - 26. DENDROBITHAIRES.

---

multipliés, en a augmenté de plus en plus l'énergie, et les cumulant dans les plus parfaits, elle a fait exister tous les animaux connus avec l'organisation et les facultés que nous leur observons." (*Anim. sans Vertèbr.* i. 123.) Thus denying to the Creator the glory of forming those works of creation, the animal and vegetable kingdom (for he assigns to both the same origin, *ibid.* 83), in which his glorious attributes are most conspicuously manifested; and ascribing them to nature, or *a certain order of things,* as he defines it (214)—a blind power, that operates necessarily (311), which he admits, however, to be the product of the will of the Supreme Being (216). It is remarkable, that in his earlier works, in which he broaches a similar opinion, we find no mention of a Supreme Being. (See his *Système des Animaux sans Vertèbres, Discours d'Ouverture.*) Thus we may say, that, like his forerunner Epicurus, *Re tollit,* dum *oratione relinquit Deum.* But though he ascribes all to *nature,* yet, as the *immediate* cause of all the animal forms, he refers to the local circumstances, wants, and habits of individual animals themselves: these he regards as the modifiers of their organization and structure (162).

Let us here note, that M. Desmoulins, in the 2d edition of Dr Magendie's *Physiology* (1825), has exhibited a system in which the principles of Cuvier and De Blainville are joined in one.

A learned and ingenious Scotsman, Mr William Sharpe Macleay, is the author of several profound and original views in natural history. The unbroken and continuous succession, or linear series, in which systematic writers had previously regarded the objects of their contemplation, was first deviated from by Lamarck, who, in his supplement to the first volume of his *Animaux sans Vertèbres*, presented the *Invertebrata* in a double subramose series, consisting of articulated and inarticulated animals. The following are the principal bases of Mr Macleay's system.[1]

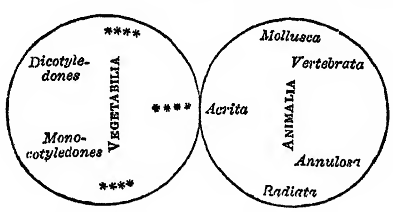
1. That all natural groups, whether kingdoms or any subdivision of them, return into themselves; a distribution which Mr Macleay expresses by circles.

2. That each of these circles is formed precisely of *five* groups, each of which is resolvable into five other smaller groups, and so on till we reach the extreme term of such division.

3. That proximate circles or larger groups are connected by the intervention of lesser groups, denominated *osculant*.

4. That there are relations of analogy between the corresponding points of contiguous circles.

The author has represented his system by tables of circles, inscribed with the names of the five primary divisions of each group. The following table exhibits his general view of the animal and vegetable kingdoms:



It will be perceived by the preceding diagram, that Mr Macleay divides the animal kingdom into five great sub-kingdoms, viz.

1. Acrita, composed of the *infusoria*, the *polypi*, the *corallines*, the *tæniæ*, and the least organized of the *intestinal worms*.

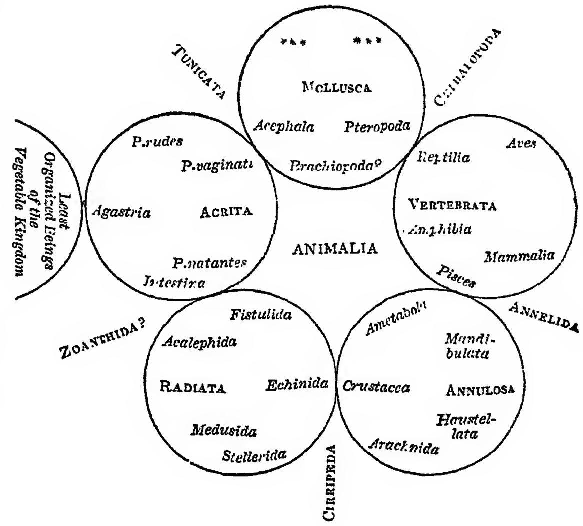
2. Radiata, containing *medusæ*, *star-fish*, *sea-urchins* or *echini*, and others.

3. Annulosa, consisting of *insecta*, *arachnida*, and *crustacea*.

4. Vertebrata, constituted by *beasts*, *birds*, *reptiles*, *amphibia*, and *fishes*.

5. Mollusca, including the numerous tribes of *shell-fish* or *marine testacea*, *fresh-water shells*, *snails*, *slugs*, &c. which, from the analogies presented by their soft or mucous substance, the peculiarities of their nervous system, and the general imperfection of their senses, appear as it were to return again to the *acrita*, though allied to the *vertebrata* by characters drawn from the possession of a heart and a circulating system.

The ensuing set of circles exhibits the further subdivision of the five sub-kingdoms into classes.



The *osculant* classes are such as are placed between the circles. In the molluscous circle two classes are still wanting to complete the quinary arrangement of that great division. According to Mr Kirby, the number *five*, assumed by Mr Macleay as a principal basis of his system, and as consecrated in *nature*, ought to yield to the number *seven*, which is consecrated both in *nature* and *scripture*. Metaphysicians enumerate *seven* principal operations of the mind, musicians *seven* principal tones, and opticians *seven* primary colours. In scripture, the abstract idea of this number is, *completion*, *fullness*, *perfection*. Mr Kirby seems to think that Mr Macleay's *quinaries* may be found resolvable into *septenaries*, in consequence of future investigations.[2]

We shall enter at greater length into a detailed expo-

To show the absurd nonplus to which this his favourite theory has reduced him, it will only be necessary to mention the individual instances which, in different works, he adduces to exemplify it. In his *Système* he supposes that the webfooted birds (*Anseres*) acquired their natatory feet by frequently separating their toes as far as possible from each other in their efforts to swim. Thus the skin that unites these toes at their base contracted a habit of stretching itself; and thus in time the web-foot of the duck and the goose was produced. The waders (*Grallæ*), which, in order to procure their food, must *stand* in the water, but do not love to *swim*, from their constant efforts to keep their bodies from submersion, were in the habit of always stretching their legs with this view, till they grew long enough to spare them the trouble!!! (13). How the poor birds escaped drowning before they had got their web-feet and long legs the author does not inform us. In another work, which I have not now by me, I recollect he attributes the long neck of the camelopard to its efforts to reach the boughs of the mimosa, which, after the lapse of a few thousand years, it at length accomplished!!! In his last work he selects as an example one of the *Moluscæ*, which, as it moved along, felt an inclination to explore by means of touch the bodies in its path: for this purpose it caused the nervous and other fluids to move in masses successively to certain points of its head, and thus in process of time it acquired its horns or tentacula!! (*Anim. sans Vertèbr.* i. 188.) It is grievous that this eminent zoologist, who in other respects stands at the head of his science, should patronize notions so confessedly absurd and childish." (*Introduction to Entomology*, by Kirby and Spence, vol. iii. p. 349.)

[1] See *Horæ Entomologicæ*, and Kirby & Spence's *Introduction to Entomology*, vol. iii. p. 12.

[2] *Introduction to Entomology*, vol. iii. p. 15. The quinary system, in its application to insects and other annulose animals, is pretty fully developed by its ingenious author in his *Horæ Entomologicæ*, already more than once referred to. An excellent paper by Mr Vigors, on the classification of birds, in accordance with the same system, will be found in the 14th volume of the *Transactions of the Linnæan Society*.

sition of the quinary system of arrangement under the articles *Entomology* and *Ornithology*.

Cuvier divides the animal kingdom into four principal branches. Setting aside all accessory and artificial characters, he proceeds upon the consideration of the essential structure of animals, and thus deduces four great groups or separate types of form, to one or other of which all the minor divisions may be ultimately referred.

In the first of these forms the brain, and the great central trunk of the nervous system called the spinal marrow, are protected by strong bony coverings—the cranium and vertebral column. To the sides of that column are attached the ribs and the bones of the anterior and posterior members. All the classes of this primary division are provided with red blood, a muscular heart, a mouth with two horizontal jaws, and special organs of vision, hearing, taste, and smell, placed in the head or upper and anterior portion. They have never more than four members; their sexes are always separate; and they nearly resemble each other in the distribution of their medullary masses, and the principal branches of their nervous system. On examining more narrowly the constituent parts of the classes which compose this great assemblage, it is easy to discover many striking analogies both of form and structure, even in those groups which are most distantly related to each other; and from the human species to the last of the fishes there exists an obvious conformity to the same general plan. The name of VERTEBRATED ANIMALS is bestowed on this division, on account of their being possessed of a vertebral column or back-bone. The following are the principal groups or classes into which it is further divisible.

FIRST PRIMARY DIVISION: ANIMALIA VERTEBRATA.

Class 1*st*. Man, mammiferous land-animals, and cetacea.
Class 2*d*. Birds.
Class 3*d*. Reptiles.
Class 4*th*. Fishes.

The second great division possesses no skeleton. The muscles are attached to the skin, which forms a soft contractile envelope; and many of the species are protected by hard coverings, commonly called shells, which are supposed to occupy in the cutaneous system of this form of animal life the same station as the mucous membrane of the preceding division. The nervous system is contained along with the viscera within this general envelope, and is composed of many dispersed portions, of which the principal, placed above the œsophagus, may be regarded as representing the brain. Of the four special senses it is impossible to discover the organs of more than two, taste and sight; and even of these the last is frequently wanting. The organs of hearing are visible only in one family. The system of circulation is however complete; there are particular organs for the performance of respiration; and the functions of digestion and secretion are almost as complicated as in the vertebrated classes. The subdivisions of this second form are called MOLLUSCOUS ANIMALS; and although the external configuration of their parts does not exhibit the same agreement as that of the vertebrated classes, there is always a corresponding resemblance in their essential structure and functions. The following are the classes of this branch of the animal kingdom.

SECOND PRIMARY DIVISION: ANIMALIA MOLLUSCA.

Class 1*st*. Cephalopoda, *e. g.* cuttle-fish, nautili, belemnites, argonauts, &c.
Class 2*d*. Pteropoda. Genus Clio, &c.
Class 3*d*. Gasteropoda. Slugs, snails, and numerous groups of turbinated shells.
Class 4*th*. Acephala. Oysters, mussels, and other bivalve shells, &c.
Class 5*th*. Brachiopoda. Terebratulæ, &c.
Class 6*th*. Cirrhopodes. Barnacle shells, &c. Lepas and Triton. (Linnæus.)

The third great preponderating form is represented by insects and other analogous classes. Their nervous system consists of two long ventral or sublateral chords, which swell out at intervals into knots or ganglia. The first of these ganglia, placed *above* the œsophagus, is analogous to the brain, although it does not exceed in size and scarcely in importance the ganglia of the lengthened cords, with which it communicates by means of a ring which embraces the œsophagus like a collar. The general covering of the body in this division is sometimes hard, sometimes soft, and is divided into segments by a certain number of transverse incisions. The muscles are always attached to the interior, and the body is usually, though not universally, provided with articulated members. It is among the classes of this form that we begin to perceive the passage from a system of circulation in closed vessels called arteries and veins, to nutrition derived from imbibition; and a corresponding passage from respiration in circumscribed organs to that performed by tracheæ or air-vessels, distributed over the whole body, is likewise observable. The organs of taste and sight are the most distinct in this branch; the organ of hearing is apparent only in a single family, although we can scarcely doubt that the sense exists in others in which the organ has not been ascertained. The following classes are ranked under this great form.

THIRD PRIMARY DIVISION: ANIMALIA ARTICULATA.

Class 1*st*. Annelides. Serpulæ, nereids, leeches, earthworms, the hair-eel, &c.
Class 2*d*. Crustacea. Crabs, lobsters, shrimps, &c.
Class 3*d*. Arachnides. Spiders, scorpions, mites, &c.
Class 4*th*. Insecta. Beetles, flies, butterflies, &c.

In the three preceding divisions, the organs of movement and of sensation are disposed symmetrically on both sides of an axis, with an anterior and posterior portion differing from each other. Among the zoophytes, which form the last great division, the organs are usually disposed in a radiated form. They approach the nature of plants in the extreme simplicity of their structure. They have no distinct nervous system, nor organs of the special senses; and it is barely possible to detect in a few of the species some slight vestige of the circulating system. Their respiratory organs are almost always on the surface of their bodies. The greater proportion of the classes exhibit no other intestine than a sack or cæcum, and the composition of the last groups of all presents only a homogeneous pulpy mass, sensible, and endowed with motion. From a consideration of their most usual forms, the classes of this order are named RADIATED ANIMALS. They are as follows:—

FOURTH PRIMARY DIVISION: ANIMALIA RADIATA.

Class 1*st*. Echinodermata. Star-fish, sea-urchins, &c.
Class 2*d*. Entozoa. Intestinal worms.
Class 3*d*. Acalephæ. Sea-nettles, actiniæ, medusæ, &c.
Class 4*th*. Polypi. Corals, madrepores, sponges, &c.
Class 5*th*. Infusoria. Infusory and other microscopical animals.

Such are the great outlines of a system which, considered in its generality, is certainly the most satisfactory which has yet appeared. Particular departments may have been filled up, modified, and perhaps improved by ingenious observers, sedulous within a limited sphere (and of these ameliorations we shall be careful to avail ourselves when we come to enter upon a detailed view of each of the classes of the animal kingdom); but the construction and position of the principal groups, their real as well as relative characters, are developed in the system of the great French anatomist, in a manner more clear and accordant with nature than in any other yet promulgated. We shall therefore in the course of this work adhere, with some slight transpositions, the reasons for which will be stated in their proper place, to the classes of Baron Cuvier. The greater extent and importance of some of these, in comparison with others, will induce us to bestow more attention and a larger space to their illustration; and as certain of the primary divisions, such as the Mollusca and Radiata, contain a greater number of classes, if not of less importance, at least by no means so strongly characterized or contradistinguished from each other as are those of the vertebrated tribes, we shall, in presenting the history and nomenclature of such classes, group them together in such a manner as to exhibit them to the reader either under one of the great primary divisions, or as an intermediate subdivision, containing one or more classes. For example, the article MOLLUSCA of this work will present consecutively under a single head the history and classification of the six classes contained in the second primary division so named;—but the four classes of vertebrated animals will be each discussed in a separate treatise. Thus mammiferous animals, birds, reptiles, and fishes, will form the articles MAMMALIA, ORNITHOLOGY, REPTILIA, and ICHTHYOLOGY. The Classes of the third primary division, viz. Annelides, Crustacea, Arachnides, and Insecta, will (with the exception of the first, referred to Helminthology) likewise be treated of under distinct heads, in the alphabetical order, of the following terms:— CRUSTACEA, ARACHNIDES, and ENTOMOLOGY. In regard to the fourth primary division, that of the radiated animals, commonly called Zoophytes, the first class, named ECHINODERMATA, will be treated of separately under its own title; the second class, *Entozoa*, which contains the intestinal worms, will be grouped with the Annelides or red-blooded worms (as above excepted from the third primary division); and these two classes will be treated of together under the article HELMINTHOLOGY. The remaining classes of the Animalia Radiata, that is to say, the Acalephæ, the Polypi, and part of the Infusoria, as they form the last links of the animal kingdom, will come to be discussed with greater propriety at the concluding stage of this work, under the head of ZOOPHYTES. Finally, that portion of the infusorial class which we have excepted in the above distribution will be found described in the present volume under the word ANIMALCULE. This completes the exposition of our zoological system.

The following enumeration exhibits a view of the terms under which the principal subjects of zoology will be explained and illustrated in the course of this work.

Systematic Arrangement.	*Alphabetical Arrangement.*
Mammalia.	Animalcules.
Ornithology.	Arachnides.
Reptilia.	Crustacea.
Ichthyology.	Echinodermata
Mollusca.	Entomology.
Crustacea.	Helminthology.
Arachnides.	Ichthyology.
Entomology.	Mammalia.
Echinodermata.	Mollusca.
Helminthology.	Ornithology.
Zoophytes.	Reptilia.
Animalcules.	Zoophytes.

ANIMAL *Magnetism*. See MAGNETISM, *Animal*.

ANIMALCULE.

ANIMALCULE, a diminutive term (from the word animal), applied by naturalists to those minute beings which become apparent in various fluids when subjected to the microscope. They were named infusory animals (*Infusoria*) by Müller, one of the most celebrated observers in this department of zoology; and the appellation, however inapplicable, now occurs in the majority of scientific publications. Of course it applies with propriety only to such species as are developed through the medium of infused substances. Now we know, that of 400 species of Infusoria (commonly so called) described by Müller himself, not a sixth part were observed in any kind of infusions; whilst the remainder inhabited the most translucent waters, and speedily died when placed in impure or corrupted liquids. Even the word animalcule (or little animal) does not convey a positive or sufficiently restricted idea in relation to this particular class; because mites and certain polypi are extremely minute in their dimensions, and equally require the aid of microscopical investigation; and thus the term microscopics (*microscopiques*), recently proposed by M. Bory de St Vincent, is not less faulty than its predecessors. The size of an animal, in fact, bears no essential relation to the other conditions of its organization; and therefore we cannot infer its nature with any certainty from a knowledge of its dimensions. At the same time it must be admitted, that the most simply organized, both of plants and animals, are also the most minute; and thus the Infusoria may be regarded as possessed of certain characters in common. We here adopt the word Animalcule, chiefly because it is the most familiar to the English reader.

The subjects of our present observations may be thus defined:—*Animals invisible to the naked eye;*[1] *more or less translucent; unprovided with members* (the caudal, and other appendices, with which certain species are furnished, being scarcely regardable as such); *no perceptible eyes; contractile in whole or in part; endowed with the sense of touch; deriving nourishment by absorption; generation* (when not apparently spontaneous, and consequently incomprehensible) *effected by division, or by the emission of gemmules or oviform bodies; inhabitants of liquids.* They are the smallest and most simple of living creatures, but not less perfect than the other tribes; for though they possess the fewest faculties, their means are in every way adequate to their wants, and their vital energies proportioned to their sphere of enjoyment.

Among microscopical animals we find many species which, in their aspect and structure, present no analogy

[1] The *Volvox globator*, and a few others, which are just discernible without the aid of a microscope, form exceptions to the above character.

to other forms of animal life: they are merely moving molecules of the simplest organization, the exact nature of which it is sometimes difficult to determine, and which involve in deeper obscurity the mysterious line of demarcation by which we so often seek in vain to separate the animal from the vegetable kingdom. If, however, the true distinction between plants and animals consists chiefly in the irritability and power of contraction possessed by the latter, then the Infusoria, which are strongly endowed with these attributes, are indeed so far removed from the vegetable kingdom, that the name of Zoophytes, or animal plants, is inapplicable to the class to which they belong. In the extreme simplicity of their structure, they no doubt present some analogy to the least complicated tribes of plants, such as the algæ and others; but it is a mere analogy, and not a connection of affinity,—for no alliance between these kingdoms has ever been demonstrated, although certain obscure phenomena may have presented difficulties in the way of our investigations. "We need not be surprised," Mr Macleay observes in his *Horæ Entomologicæ*, "that several of the Linnæan algæ should be still hovering in a state of uncertainty between the two kingdoms; but, on the contrary, be prepared to expect additional proofs of the analogy which the two great divisions of organized matter bear to each other. The Agastria, or Agastraires of De Blainville, are indeed *animals*, though they have neither distinct organs of sense, alimentary canal, nor even mouth,—though they have, in short, so far as our present knowledge of them would lead us to believe, no internal digestion whatever to execute, but trust for nourishment, like plants, to the absorption of their external pores. They must be esteemed animals on account of their peculiar irritability; but are vegetables in almost every other respect."

Our knowledge of the history of animalcules resulted from the improvement of the microscope by Hartzoeker and Leeuwenhoeck. The ancients were consequently unacquainted with the mysteries of this "invisible world;" and we are thus saved the tedium of a lengthened bibliographical investigation. Notwithstanding the observations of Hill, Baker, Ledermuller, Goeze, Gleicken, Roësel, Pallas, Needham, Spallanzani, and several other minute and laborious inquirers, it may be said that this branch of zoology only assumed a truly scientific form in consequence of the labours of a distinguished Danish naturalist, Otho Frederic Müller. His earlier works, such as the *Vermium Terrestrium et Fluviatilium Historia*, and the *Zoologiæ Danicæ Prodromus*, presented very decided improvements in the knowledge and classification of animalcules. These emendations were transferred by Gmelin to the 13th edition of the *Systema Naturæ* of Linnæus, in which animalcules form the fifth order of the class of Vermes. But the work which, had the rest been wanting, would alone have immortalized the name of Müller, appeared (posthumously) in 1786, under the title of *Animalcula Infusoria, Fluviatilia et Marina*. It is illustrated by 50 plates, containing figures of 360 species variously represented. A later and very useful compendium of knowledge regarding microscopical animals forms a portion of the *Encyclopédie Méthodique* (46th livraison), in which Bruguière has reproduced the plates of Müller, with the addition of several others of equal accuracy from the third volume of Roësel's *Insecten-belustigungen*. The reader will there find descriptions of 28 plates, containing nearly 1100 figures representing 385 animalcular species.

Before proceeding further, we shall present a brief view of the system of Müller, as of high importance in itself, and the fundamental basis of the more recent and improved arrangements. It includes, however, several genera which are not now classed among the animalcular tribes. He divides the CLASS of ANIMALCULA INFUSORIA as follows:

ORDER I.—*No External Organs.*

* *Thickened.*

Genus 1. *Monas;* body punctiform. 10 species.
2. *Proteus;* body variable. 2 species.
3. *Volvox;* body spherical. 12 species.
4. *Enchelis;* body cylindrical. 27 species.
5. *Vibrio;* body elongated. 31 species.

* * *Membranous.*

6. *Cyclidium;* body oval. 10 species.
7. *Paramæcium;* body oblong. 5 species.
8. *Kolpoda;* body sinuous. 16 species.
9. *Gonium;* body angular. 5 species.
10. *Bursaria;* body excavated. 5 species.

ORDER II.—*External Organs.*

* *Naked.*

11. *Cercaria;* smooth, tailed. 22 species.
12. *Trichoda;* haired or ciliated. 89 species.
13. *Kerona;* with horny appendices. 14 species.
14. *Himantopus;* with cirrated appendices. 7 species.
15. *Leucophra;* the entire surface ciliated. 26 species.
16. *Vorticella;* orifice ciliated. 75 species.

* * *Furnished with a Shell.*

17. *Brachionus;* orifice ciliated. 22 species.

In the year 1815 Lamarck published the first part of his *Animaux sans Vertèbres*, a work which forms an epoch in the history of the inferior tribes. In this signal publication the author adopts a different course from that usually followed by systematic writers; and pursuing an ascending rather than a descending scale, he commences with the lowest and least complex species, viz. the Infusoria. From this class, however, he rejects all those species in which any kind of complication of organs is apparent. All the genera so distinguished are referred by him to the first order of the second class of the animal kingdom, called POLYPI, under the title of *Polypi ciliati;* and the true and restricted Infusoria are thus defined: *Microscopical animals, gelatinous, transparent, polymorphous, contractile; having no distinct mouth, nor constant, determinable, internal organs; generation fissiparous or sub-gemmiparous.* The genus Kerona, it may be further remarked, is in this system united to the Himantopus of Müller, while the genus Cercaria of that author is divided into two. Thus the class Infusoria of Lamarck, composed of two great sections, the naked and the appendiculated, may be said to correspond to the first 14 genera of the Danish naturalists.

Cuvier, in the *Règne Animal* (1817), places the Infusoria as a part of his fourth great division, the zoophytical or radiated animals. The term *radiated* was originally bestowed on a numerous tribe of animals, such as the Asterias and others, on account of their arms or tentacula being extended in a radiated or star-like form; but it certainly applies unfitly to the true Infusoria of Lamarck, which possess nothing resembling a radiated structure. It cannot, however, be always expected that a general term of wide import should apply with etymological accuracy to every part of the extensive series which it is intended to embrace. Cuvier then divides his Infusoria into two orders, *Les Rotifères*, and *Les Infusoires homogènes*, the former of which correspond to the ciliated polypi of La-

marck, the latter to the Infusoria properly so called of that author.

According to M. de Blainville, the class Infusoria can scarcely be regarded as established upon a natural foundation. The organization of its component tribes is so various as to lead to the belief that a more precise knowledge would show that several of those tribes belong to different types of the animal kingdom. Some, as the genus Brachionus, are symmetrically formed both as regards their bodies and appendages, and are protected by a horny or crustaceous covering. Others, as Vibrio, Paramæcium, &c. have the body elongated, depressed, vermiform, and without appendages. A third division exhibit a radiated structure, as for example the Vorticellæ, which, however, we have already stated, are now seldom classed among the Infusoria. Many genera, such as Proteus, Volvox, Monas, are amorphous, or without determinate form, and cannot be referred to any other known type of the animal kingdom. They are regarded by many as the elementary molecules of all animal life, and in their structure no other than the cellular tissue is observable. They may be said to be dependent on external circumstances, instead of being able, like other animals, to modify or control them; and their usually spherical form is the necessary result of an equal pressure of water on all sides of a frail and yielding texture. M. de Blainville considers the genera *Brachionus*, *Urcelaria*, *Cercaria*, *Furcularia*, *Kerona*, *Trichocerca*, and *Himantopus*, as belonging to the type of *Entomozoaires* or articulated animals, and especially to the class Heteropoda, order Entomostraca. Many species of *Vibrio* he regards as Apodes, as well as *Paramæcium* and *Kolpoda*. Other species of the genera *Vibrio* and *Cyclidium* ought rather to be ranged with the Planaria; and in the genus *Leucophra* there is even a species which M. de Blainville is inclined to look upon as an Ascidia! Finally, the genera *Gonium*, *Proteus*, *Volvox*, and *Monas*, if they are really animals, appear to form a distinct type, which may be called Amorphes or Agastraires; so named from the circumstance of their having neither determinate form nor reduplication of the external envelope for the formation of a stomach, as in all other true animals.

Such is a brief exposition of the views of one of the most distinguished physiological inquirers of the present day. It may serve, if for nothing more, at least to show the unsettled state of opinion concerning these extraordinary creatures. In regard to this, however, we may rest assured that, in the future progress of science, the class Infusoria, as at present constituted, will suffer an entire dismemberment, and its component parts will be referred to various groups of the animal kingdom, some of them widely distant from each other.

In the year 1826 a full and most elaborate classification of microscopical animals was given to the world by M. Bory de St Vincent. As it is the singular mode of existence of animalcular beings, their general economy in the field of nature, the actual conditions of their organization, and the state of their limited faculties so far as these can be ascertained, with which we are chiefly interested—so, in our systematic view of this extraordinary class, we shall merely present to our readers the characters of the principal genera, and of a few of the most remarkable species which they contain. But, as some may be desirous to possess at least a sketch of the full extent and condition of this intricate subject, we have constructed the accompanying tabular scheme of the orders, families, and genera of microscopical animals, according to the views of M. Bory de St Vincent, the latest and most assiduous writer on this department with whose labours we are acquainted. We have thought it advisable to retain the terms of the original language, lest, by inadvertence or misconception on the part of the translator, any additional obscurity should rise around a subject already sufficiently encumbered. (*See Tabular View on the next page.*)

The order Gymnodes of Bory de St Vincent nearly corresponds to the entire class Infusoria of Lamarck; and although the observations by which he illustrates his arrangement partake of the accustomed defects of the French philosophy, the facts which he details, if not the theoretical views which he inculcates, are worthy of an attentive consideration. These mysterious creatures are observed to swim with astonishing rapidity; and although their bodies are usually diaphanous, it has hitherto proved impossible, even by the aid of the most powerful glasses, to ascertain by what natural mechanism these movements are effected. They direct their courses by a discretionary power, in one direction rather than another, avoiding and turning round opposing obstacles, according to the necessities of the case—discerning, as the process of evaporation proceeds, the points in which they may prolong their existence, and flocking in crowds to those places where they are best screened from the overpowering brilliancy of the reflecting mirror. They thus appear to possess volition, which we are accustomed to regard as a result dependent on the faculties of perception and comparison.

The principal obstacle to our understanding the essential nature of animalcules results from their want of a nervous system, which, in ourselves, and in all the intermediate classes of the nature of whose consciousness we have even a vague idea, we regard as the *sine qua non* of sensation and intelligence. Voluntary motion without muscular action is also a circumstance which we cannot very clearly comprehend. But as there may be "more things in heaven and earth than are dream't of in our philosophy," we must not reject facts, that is to say appearances which present themselves under the same determinate and uniform aspect to various unprejudiced ob servers, merely because they do not coincide, or may possibly controvert or interfere, with a previous hypothesis. On the other hand, the extreme softness of texture, and excessive minuteness, of most of the animalcular species, render anatomical investigation almost impossible; and naturalists may have erred in supposing the absence of what they are merely unable to perceive and demonstrate.

It is in truth impossible to discover any traces of the nervous system, even among several tribes of animals in other respects much more highly organized than the subjects of our present inquiry. Trembley's examination of the Polypus threw no positive light upon the matter; nor did Gade's dissections of the larger Medusæ enable him to discover either muscular or nervous fibres. According to M. Bory de St Vincent, the nervous system is one of the last to be developed. To the perfect simplicity of the Monads, the first perceptible addition is that of a central cavity, or rudimentary intestinal sac, which we find to occur even before the existence of a mouth. Next appears an opening to this canal, which serves both for the reception of nourishment, and the rejection of excrementitious parts where such exist. The hairs and cirrated appendages which ensue in still more complicated species have been regarded as the early rudiments of the respiratory system; and even a heart, or central organ of a circulating fluid, is partly developed before the appearance of any nervous chords. The earliest, most general, and perhaps the only indispensable function of animal life, is that of nutrition. But the materials of nutrition are so different, and their modes of reception so various, that the exercise of this

Table of the Orders, Families, and Genera of Animalcules, according to a new Analytical Method. By Bory de Saint-Vincent.

MICROSCOPIQUES.

ORDRES. — FAMILLES. — GENRES.

- **Sans aucune apparence de test.**
  - **Parfaitement glabres, sans cils ni cirres vibratiles ... GYMNODÉS.**
    - Dépourvus d'appendices quelconques, soit caudiformes ou autres.
      - Jamais linéaires ni anguiformes.
        - De formes invariables.
          - Où chaque molécule est ou peut devenir un animal particulier.
            - Molécules toujours isolées, et formant autant d'individus ... **MONADAIRES.**
              - Corps anguleux, non arrondi ... 1. *Lamellina.*
              - Corps arrondi, jamais anguleux.
                - Sphérique.
                  - Sans point central ... 2. *Monas.*
                  - Marqué d'un point central ... 3. *Ophthalmopl*
                - Ovalaire comprimé ... 4. *Cyclidium.*
            - Molécules groupées, et comme formant un individu en commun ... **PANDORINÉES.**
              - Où les molécules groupées ne sont revetues d'aucune enveloppe commune.
                - Se groupant en sphérules ... 5. *Uvella.*
                - Se groupant en lames ... 6. *Pectoralina.*
              - Où les molécules groupées sont englobées dans une enveloppe commune ... 7. *Pandorina.*
          - Où les molécules demeurent irrévocablement asservies à une vie commune, et ne se désunissent jamais pour vivre isolément ... **VOLVOCIENS.**
            - Corps sphérique.
              - Où la molécule interne laisse un anneau translucide autour du corps ... 8. *Gyges.*
              - Où la molécule interne remplit le corps sans laisser comme un anneau translucide circulaire ... 9. *Volvox.*
            - Corps pyriforme ... 10. *Enchelis.*
        - De forme plus ou moins variable.
          - Corps applani et ne s'excavant jamais ... **KOLPODINÉES.**
            - Corps jamais plissé à sa surface.
              - Antérieurement denté ... 11. *Triodonta.*
              - Non denté antérieurement.
                - Sinueux ... 12. *Kolpoda.*
                - Amorphe ... 13. *Amiba.*
            - Corps muni d'un pli à sa surface ... 14. *Paramæcium.*
          - Corps excavé, ou susceptible de s'excaver ... **BURSARIÉES.**
            - Corps se creusant en bourse.
              - Dépourvu de cloison interne ... 15. *Burraria.*
              - Présentant un rudiment de cloison interne ... 16. *Hirundinella.*
            - Corps creusé en godet ... 17. *Craterina.*
      - Linéaires ou anguiformes ... **VIBRIONIDES.**
        - Corps opaque.
          - Roulé en spirale discoïde ... 18. *Spirilina.*
          - Non roulé en spirale discoïde ... 19. *Melanella.*
        - Corps diaphane.
          - Atténué aux deux extrémités ... 20. *Vibrio.*
          - Obtusé.
            - Atténué en cou, avec un bouton en manière de tête ... 21. *Lacrimatoria.*
            - Non atténué en cou, et sans bouton en manière de tête ... 22. *Pupella.*
    - Munis d'un ou de deux appendices caudiformes ou autres.
      - Normaux.
        - Un seul appendice caudiforme terminal ... **CERCARIÉES.**
          - Corps cylindracé.
            - Polimorphes ou du moins contractiles.
              - Où l'appendice est une continuation du corps graduellement aminci ... 23. *Raphanella.*
              - Où l'appendice est comme implanté en queue ... 24. *Histrionella.*
            - Non contractiles ni polymorphes.
              - Sans carène sur aucun coté du corps ... 25. *Cercaria.*
              - Corps présentant une carène sur un de ses cotés ... 26. *Turbinella.*
          - Corps comprimé.
            - Point d'appendices latéraux.
              - Appendice caudal non infléchi sur un côté du corps ... 27. *Zoosperma.*
              - Appendice caudal infléchi sur un côté du corps ... 28. *Virgulina.*
            - Deux petits appendices latéraux outre le caudiforme ... 29. *Tripos.*
        - Appendice double ou bifide ... **URODIÉES.**
          - Corps non vaginiforme, ni distinctement urcéolé.
            - Non terminé en une sorte de tete.
              - Les deux appendices distincts jusqu'à leur insertion.
                - Continus avec le corps, et non infléchis ... 30. *Furcocerca.*
                - Comme implantés au corps, et infléchis ... 31. *Trichocerca.*
              - Les deux appendices se fourchant sur un pédicule et non sur le corps ... 32. *Ty.*
            - Se terminant en une sorte de tete ... 33. *Cephalodella.*
          - Corps subvaginiforme ou urcéolé.
            - Appendices terminaux ... 34. *Leiodina.*
            - Appendices latéraux ... 35. *Kerobalana.*
      - Genre anomal; appendices en forme de herse épars sur l'une des surfaces de l'animal ... 36. *Tribulina.*
  - **Où se distinguent des cils ou des cirres vibratiles.**
    - **Où des cils répandus sur toute la surface du corps, ou disposés diversement sur quelqu'une de ses parties, ne forment point d'organe vibratile particulier, et encore moins de rotatoires complets ... TRICHODÉS.**
      - Corps totalement dépourvu d'appendices caudiformes ou autres.
        - Où les cils couvrent ou environnent la totalité du corps ... **POLYTRIQUÉES.**
          - Velus.
            - Corps ni fissé, ni appendiculé ... 37. *Leucophra.*
            - Corps fissé, ou appendiculé à l'une des extrémités ... 38. *Diceratella.*
          - Ciliés.
            - Corps non antérieurement atténué en cou ... 39. *Peritricha.*
            - Corps antérieurement atténué en cou ... 40. *Stravolæma.*
        - Où les cils, ne couvrant pas ou n'environnant pas la totalité du corps, y sont répartis en faisceaux ou séries ... **MYSTACINÉES.**
          - Cils en un seul faisceau ou série.
            - En un faisceau terminal.
              - Corps antérieurement atténué en cou que termine un bouton en maniere de tete ... 41. *Phialina.*
              - Corps non antérieurement atténué en cou, et que ne termine aucun bouton ... 42. *Trichoda.*
            - En une série latérale.
              - Corps sub-urcéolé ... 43. *Ypsistoma.*
              - Corps jamais sub-urcéolé ... 44. *Plagiotricha.*
          - Cils en plus d'un faisceau ou série.
            - Corps antérieurement fissé, ou les cils forment comme deux moustaches ... 45. *Mystacodella.*
            - Corps non antérieurement fissé.
              - Sans apparence d'ouverture buccale que bordent les cils.
                - Cils de meme nature, dont les uns ne sont ni plus longs ni plus rigides que les autres.
                  - En deux groupes.
                    - Sérialement ... 46. *Oxytricha.*
                    - Fasciculés ... 47. *Ophrydia.*
                  - En trois groupes ... 48. *Trinella.*
                - Cils de diverse nature, dont les uns sont plus longs ou plus rigides que les autres ... 49. *Kerona.*
              - Avec une sorte d'ouverture buccale sur un coté que bordent les cils ... 50. *Kondyliostoma*
      - Corps terminé en appendices caudiformes ... **URODÉES.**
        - Appendice caudal simple ... 51. *Ratulus.*
        - Appendice caudal double ... 52. *Diurella.*
    - **Ou les cirres vibratiles, disposés sur les bords ou aux alentours d'un orifice buccal, deviennent vivement vibratiles.**
      - **Où les cirres vibratiles ne forment pas de rotatoires complets distincts ... STOMOBLÉPHARÉS.**
        - Corps urcéolé ... **URCEOLARIÉES.**
          - Corps non contractile ni polymorphe ... 53. *Myrtilina.*
          - Corps contractile, plus ou moins polymorphe.
            - Vaguant, et non stipité.
              - Urcéole rempli par un corps qui se prolonge centralement en mammelon ... 54. *Rinella.*
              - Urcéole entièrement évidé.
                - Postérieurement épais, obtus et non atténué ... 55. *Urceolaria.*
                - Postérieurement atténué en pointe, et tubiforme ... 56. *Stentorina.*
            - Stipité, et se fixant ... 57. *Sinantherina.*
        - Corps vaginé ... **THIKIDÉES.**
          - Corps fixé dans le fourreau.
            - Appendice caudal simple.
              - Deux filamens tentaculaires antérieurs ... 58. *Filina.*
              - Point de filets tentaculaires quelconques ... 59. *Monocerca.*
            - Appendice caudal composé.
              - Bifide ... 60. *Furcularia.*
              - Trifide ... 61. *Trichocerca.*
          - Corps libre et non adhérant dans le fourreau ... 62. *Vaginicola.*
      - **Où les cirres vibratiles forment des rotatoires complets et distincts ... ROTIFERES.** ... (Cet Ordre ne contient qu'une famille) ... **ROTIFÈRES.**
        - Corps contenu dans une capsule en ampoule où il semble ne pas adhérer.
          - Rotatoires non variables, constamment doubles.
            - Sessiles ... 63. *Foliculina.*
            - Pédicellés ... 64. *Bakerina.*
          - Rotatoire variable d'un à quatre lobes ... 65. *Tubicolaria.*
        - Corps non contenu dans une capsule en ampoule.
          - Corps non vaginé, rotatoire bilobé ... 66. *Megalotrocha.*
          - Corps vaginé, rotatoires complètement distincts ... 67. *Ezechielina.*
- **Corps protégé par un test ... CRUSTODÉS.**
  - Munis d'appendices, soit en queue, soit en cornes, et postérieurs.
    - Munis de cirres vibratiles ... **BRACHIONIDES.**
      - Cirres vibratiles formant des rotatoires complets.
        - Test capsulaire urcéolé.
          - Corps terminé par une queue.
            - Bifide ... 68. *Brachionus.*
            - Simple ... 69. *Siliquella.*
          - Sans queue ... 70. *Keratella.*
        - Test univalve en carapace.
          - Queue bifide terminale ... 71. *Tricalama.*
          - Queue non bifide, sub-centrale ... 72. *Proboskidia.*
      - Cirres vibratiles ne formant que de simples faisceaux.
        - Test non urcéolé.
          - Univalve.
            - Queue sub-centrale ... 73. *Testudinella.*
            - Queue terminale ... 74. *Lepadella.*
          - Bivalve ... 75. *Mytilina.*
        - Test urcéolé ... 76. *Squatinella.*
    - Dépourvus de cirres vibratiles ... **GYMNOSTOMÉES.**
      - Test capsulaire urcéolé ... 77. *Silurella.*
      - Test non capsulaire.
        - Bivalve ... 78. *Colurella.*
        - Univalve ... 79. *Squamella.*
  - Dépourvus de tout appendice postérieur quelconque ... **CITHAROIDÉES.**
    - Des cirres à la partie antérieure seulement ... 80. *Anourella.*
    - Des cirres aux deux extrémités antérieure et postérieure.
      - Nageant le coté convexe du test en dessous, comme un bateau ... 81. *Plœsconia.*
      - Nageant le coté convexe en dessus, comme une tortue ... 82. *Coccudina.*

function by no means necessitates the existence of a mouth, a stomach, or an alimentary canal; for an increase of parts may be effected even through the medium of imponderable or elastic fluids, and by imperceptible and superficial pores.

The exterior of an infusory animal may be compared to the interior of one of the higher classes, in which nutrition is carried on by the reception of the chyle by the absorbent pores. These pores are external among the Infusoria, and the process of absorption is with them analogous to that of plants, in which there is a direct reception and appropriation of fluids from the earth and air, without any previous preparation in a central cavity or stomach. Zoophytes in general have indeed been called the cryptogamia of the animal kingdom. According to Carus, the Infusoria ought to be regarded merely as little cells, partially filled with lymph, and possessed of the powers of nutrition and locomotion; and thus the infinite changes and variations perceptible in their forms may be supposed to be produced by the various degrees in which this fluid is collected at one or other of the points of their bodies. In the opinion of that anatomist, a more complete developement of the organs of motion, and indeed of the whole organization, is inseparably united with the appearance of a distinct nervous system. This may be true as a general rule, but not as a universal principle; for the Medusa has more apparent voluntary motion than the Asterias, though the former is destitute of those nerves which in the latter make their first appearance in the shape of a pale thread-like ring surrounding the œsophagus. It is this ring around the upper extremity of the alimentary canal which, in the molluscous and articulated classes, we shall afterwards find to constitute the most uniform and most essential portion of the nervous system. The Medusæ, just referred to, being almost of the same specific gravity with water, are easily carried by currents, and moved about from place to place by the action of the waves, or even (as in the case of *Holothuria physalis*) by the winds; but Carus and other writers have assuredly erred in doubting that they execute a voluntary locomotion; for that they do so in a very decided and graceful manner must be obvious to all who have attended to these animals in their native haunts along the shores, or among the land-locked waters of the beautiful firths of Scotland.

The mysteries revealed by the glasses of Leeuwenhoeck were at first regarded as beyond belief. The uncertainty of microscopical investigations, in consequence of which so much was supposed to depend on the imagination of the beholder, was alleged against them; and even at an after-period, when men of sober judgment and the most industrious application had confirmed the experience of the indefatigable Dutchman, the wit of Voltaire did not disdain to throw its cutting sarcasm over the disciples of the "anguilles de la pâte et du vinaigre." We hope it is now admitted, that however frequently those who endeavour to expound the mysteries of nature may fail in their attempts at elucidation, yet that there is nothing in the manifold works of Omnipotent Wisdom which, if duly studied and rightly understood, would not conduce to our wellbeing and happiness; and that a single square inch of water, with its many millions of animalcular atoms, is in truth as wonderful a work of divine intelligence, and as interesting a field for human investigation, as the starry galaxy of heaven.

> In his tam parvis, atque tam nullis, quæ ratio!
> Quanta vis! quam inextricabilis perfectio!

And if a heathen philosopher (Pliny) has so expressed his almost reverential admiration, is it not to be deplored that those whose labours might be carried on under the influence of a purer light, seem as often degraded as exalted by the contemplation of their Creator's works; and, referring all to the powers of nature, or some other indefinite abstraction, refuse to recognise, amid so many wonders, the "Good Supreme" from whom these and other mightier wonders have proceeded? It is in the study of the subject with which we are now engaged, and the analogous pursuits of physiology, where the completion of the most perfect design and the happiest results of superhuman forethought are so constantly manifested, that we frequently meet, where we should least expect it, with the sneer of the sceptic, or the impious ridicule of the unbeliever. How different are the sentiments of one who combines the piety of the Christian with the genius of the poet and philosopher. "But about the time of its invention (the invention of the telescope), another instrument was formed, which laid open a scene no less wonderful, and rewarded the inquisitive spirit of man with a discovery which serves to neutralize the whole of this argument. This was the microscope. The one led me to see a system in every star; the other leads me to see a world in every atom. The one taught me that this mighty globe, with the whole burden of its people and of its countries, is but a grain of sand on the high field of immensity; the other teaches me that every grain of sand may harbour within it the tribes and the families of a busy population. The one told me of the insignificance of the world I tread upon; the other redeems it from all its insignificance; for it tells me, that in the leaves of every forest, and in the flowers of every garden, and in the waters of every rivulet, there are worlds teeming with life, and numberless as are the glories of the firmament. The one has suggested to me, that beyond and above all that is visible to man, there may lie fields of creation which sweep immeasurably along, and carry the impress of the Almighty's hand to the remotest scenes of the universe; the other suggests to me, that within and beneath all that minuteness which the aided eye of man has been able to explore, there may be a region of invisibles; and that, could we draw aside the mysterious curtain which shrouds it from our senses, we might then see a theatre of as many wonders as astronomy has unfolded, a universe within the compass of a point so small as to elude all the powers of the microscope, but where the wonder-working God finds room for the exercise of all his attributes, where he can raise another mechanism of worlds, and fill and animate them all with the evidence of his glory."[1]

Although we cannot hope to derive the same amusement or advantage from the study of each of the animalcular species considered separately, as we do from the consideration of the history of many of the higher animals, yet, in a philosophical point of view, a knowledge of the general attributes of the class presents several highly important objects; and their obscure origin, their singular organization, and more singular mode of existence, cannot fail to excite our unfeigned wonder and admiration. They can scarcely be described otherwise than by a negation of all those characters which constitute the life, power, and activity of other beings; they have no head, no eyes, no muscles, no blood-vessels, no nerves, no determinate organs for respiration, generation, or digestion—and yet they are endowed with life.

The animal nature of the Infusoria has indeed been denied by many; but such is the regular gradation from the most simply organized of the monadal forms to the much

---

[1] Chalmers's *Astronomical Discourses*. p. 112

more complicated structure of the Polypi, which present, under a remarkable aspect, such unequivocal characters of animality, that it is impossible to draw the line of demarcation; and if we admit the life of the one we can scarcely doubt that of the other. Yet many of the Infusoria appear to present the very lowest conceivable point to which animal life can be reduced.

The structure of an animal, the individual existence of which is preserved by the absorption of a circumambient fluid, and the continuance of whose species is effected by the division or separation of a part of its own body, might, *a priori*, be supposed to be of the most simple kind. "We may rest assured," observes Lamarck, "that whenever an organic function is itself unnecessary, the special organ by which it is usually performed will not be found to exist." It is indeed by considering the nature of the Infusoria that we are enabled to form a proper idea of the simplest condition of animal life; and the invention of the telescope was not of higher importance to the astronomer, than that of the microscope to the physiological naturalist. There are few subjects of reflection more interesting than the uses which philosophers of an enlightened age have deduced and matured from the scanty knowledge of a barbarous people. Glass, a material known at an early period to the Asiatic nations, and once estimated at its weight in gold, has become in the hands of Europeans of more value than the finest gold. Whoever polished the first lens may be said to have laid the foundation of an instrument destined to discover thousands of celestial worlds above and around us, and an unseen world of wonders beneath our feet. "Indeed," says Cuvier, "it could not be expected that those Phœnician sailors who saw the sand of the shores of Bœtica transformed by fire into a transparent glass, should have at once foreseen that this new substance would prolong the pleasures of sight to the old; that it would one day assist the astronomer in penetrating the depths of the heavens, and in numbering the stars of the milky way; that it would lay open to the naturalist a miniature world as populous, as rich in wonders, as that which alone seemed to have been granted to his senses and his contemplation; in fine, that the most simple and direct use of it would enable the inhabitants of the coast of the Baltic Sea to build palaces more magnificent than those of Tyre and Memphis, and to cultivate, almost under the frost of the polar circle, the most delicious fruits of the torrid zone."[1]

The faculties of the most simple infusory animals, it has been observed, are reduced to such as are common to all living beings, and to that *irritability* which results from their animal nature; and their bodies are destitute of special organs, precisely because their extremely limited faculties neither require nor admit of such organs being exercised. The chief interest to be derived from the study of this class of beings results, according to Lamarck, from the view with which such study presents us of the ultimate point to which the organization of an animal is capable of being reduced; and, among all the wonders of the creation, he regards as the most surprising the existence of animal life in such inconceivably frail and simple bodies as the least complicated of the animalcular species. It is not, however, to be said that "nature was incapable of forming special organs from the materials of these frail gelatinous bodies," but rather that the all-wise Author and Ruler of Nature has seen fit to form them in what to us may appear a destitute and incomplete condition, merely because their structure does not fulfil those other conditions which, erroneously, we have sought to establish as the indispensable bases of animal life. They truly show how confined a knowledge *our* limited faculties enable us to gain of His unlimited power; for they not only present no analogy to other more accustomed forms of life, but almost seem to exist in direct opposition to those laws in accordance with which we "live, move, and have our being."

Infusory animals, commonly so called, are found in the fresh and saline waters of all countries. They occur both naturally, if we may use the term in a contradistinctive sense, and as the apparent result of infused animal and vegetable substances. According to Leeuwenhoeck, the milt of a cod-fish contains more animalcules than there are individuals of the human race existing on the face of the earth; and he calculated that 10,000 might be held within the bulk of a grain of sand. The size of many bears the same relation to that of a mite as the dimensions of a bee do to those of an elephant; and the most powerful microscopes frequently discover nothing more than merely perceptible points in motion. Flour and water made to the consistence of book-binders' paste, exposed in an open vessel, and frequently stirred to prevent the surface from growing hard, will in a few days be found to contain millions of animalcules. The thin pellicle which grows on the surface of an infusion of common black pepper also produces an innumerable congregation of minute beings. Of these and others the real origin is still exceedingly obscure; and both Müller and Spallanzani maintained the improbable opinion that they fell from the air. Their subsequent increase or multiplication is obviously effected in different and very singular ways. Such as are spherical are usually propagated by minute portions, which, though they burst from the anterior of the animalcule itself, cannot be called eggs; and such as are of a depressed or flattened form continue their race by *cuttings* or divisions of their own bodies. We first observe a line or groove, longitudinal or transverse, according to the species; and ere long a notch or incision is perceptible at one or other or both of the ends of that apparent line. This notch increases across or longitudinally, till at last a portion is separated or cut off, or the original animal is divided into two, and each assumes the form and nature of their mutual predecessor. These new objects retain for some time their natural shape, and then in their turn give rise to one or more individuals by a similar separation of parts. Lamarck seems to be of opinion (*Philosophie Zoologique*, tome ii. p. 120 and 150) that this multiplication by division, and that by the emission of gemmules or oviform portions, are modifications of one and the same natural process;—that substantially each is the result of an extension and separation of parts, which take place when the parent individual has reached the final term of its increase. It is in fact the same excess of nourishment and growth of particular parts that, even in the higher classes, give rise to the germ of separate life, physically considered, although in regard to these the additional process of fecundation is required. It is the new light which may be gathered from the observation of the minutest of the animalcular tribes that renders their study both interesting and important to the physiologist; and it is the belief of some, that a persevering study of the history of microscopical animals will one day enable us to withdraw the mysterious veil which still conceals from our view the most important secrets of nature.

The systematic arrangement of animalcules which we propose to follow in this place is nearly that of Lamarck,

[1] *Réflexions sur la Marche actuelle des Sciences*, &c. read to the Institute of France in April 1816.

which is itself founded on the systems of Müller and Bruguière. The French naturalist includes in his system only such species of the same class described by Müller as are destitute of a mouth.

ORDER I.—NAKED INFUSORIA.

Body extremely simple, apparently homogeneous, unprovided with organs or external appendages.

The naked Infusoria are the smallest and simplest of those animals which are cognizable by the senses of man. When we expose water to air and light, especially if it contains an infusion of animal or vegetable remains, we speedily perceive, by the assistance of the microscope, a variety of animalcules. These are divided into two sections.

SECTION I.—BODY THICK.

Of this section the bodies present such a perceptible degree of thickness as removes them from the simply membranous state.

GENUS MONAS.—Body extremely small, of the simplest construction, transparent, punctiform.

The Monads are the smallest and least organized of living creatures. We have indeed scarcely any proof of their animal life, except that they are moving corpuscles, allied to the genus Volvox, the animality of which is undoubted. They have neither mouth nor alimentary canal, nor any apparent organs. They live by absorption, and are found in tranquil, but rarely in limpid waters. They are produced in infusions of animal and vegetable substances.

Sp. 1. *Monas termo.*—An extremely minute gelatinous point, scarcely perceptible even with the aid of a powerful lens, and frequently disappearing under a strong light in consequence of its perfect transparency. This species is common in ditch-water, and in numerous infusions. See Plate XLII. fig. 1. These minute creatures being the earliest discernible evidence of animal life, and the last result to which the higher and more perfect forms can be reduced by infusion, have been called the alpha and omega of all organized existence. Their history has given rise to many curious views, and more absurd speculations.

Sp. 2. *Monas atomus.*—White, with a variable dark-coloured spot, which appears to change its position. This species was found in sea-water which had been kept an entire winter, but was not very fetid. See Plate XLII. fig. 2 and 3.

Sp. 3. *Monas punctum.*—Nearly black, of a sub-cylindrical form. Found in the infusion of the pulp of a pear.

Sp. 4. *Monas lens.*—Hyaline, of an ovoid form. Found in all kinds of waters. Multiplies by spontaneous incision.

Sp. 5. *Monas pulvisculus.*—Hyaline, with a greenish margin. Found in the waters of marshes. This species has been lately regarded as an *enchelis*. Indeed, so great is the difficulty of microscopical investigation, and such indefatigable patience is required in order to see things as they really are, that the species and genera of this class of beings are frequently transposed and altered in their relative position and arrangement, in consequence of the very dissimilar views which different observers have taken of the same object.

As it would be inconsistent with our present limits to describe more than a few species of each genus, we shall content ourselves with the preceding Monads. "How many kinds," observes Mr Adams, "there may be of these invisibles, is yet unknown, as they are discerned of all sizes, from those which are barely invisible to the naked eye, to such as resist the force of the microscope, as the fixed stars do that of the telescope, and, with the greatest powers hitherto invented, appear only as so many moving points."

GENUS VOLVOX.—Body very simple, transparent, spherical or ovoid, revolving on itself as on an axis.

With the exception of one species (*V. globator*) the volvoces are invisible to the naked eye. Under the microscope they assume the aspect of small gelatinous masses, which sometimes present an oval form. In some the body seems composed of numerous smaller globules united in one common mass. There is reason to suppose that these interior bodies are afterwards propelled outwardly, and become separate individuals. The species occur both in fresh and salt waters, and in vegetable infusions. They derive their generic name from the manner in which they turn or revolve upon their axis. Leeuwenhoeck describes an animalcule "a thousand times smaller than a louse's eye, which exceeded all the rest in briskness," and turned itself round as it were upon a point, with the celerity of a spinning-top. The genus is divisible into two sections.

* *Interior of the body apparently simple and homogeneous.*

Sp. 1. *Volvox punctum.*—Spherical, blackish, with a central lucid point. Of this species many are sometimes seen together in their passage through the water. They occasionally move as if subjected to the influence of a whirlpool, and then separate. Numerous in fetid sea-water.

Sp. 2. *Volvox granulum.*—Spherical, green, periphery hyaline. Dwells in the water of marshes.

Sp. 3. *Volvox globulus.*—Globular, sub-obscure behind. This species is ten times larger than the Monas lens. It occurs in most vegetable infusions, and moves with a slow fluttering motion. Plate XLII. fig. 4.

** *Interior of the body exhibiting smaller corpuscles.*

Sp. 4. *Volvox pilula.*—Spherical, with greenish internal globules. In those pure waters which nourish the *Lemna minor*. Plate XLII. fig. 5.

Sp. 5. *Volvox lunula.*—Roundish and transparent, and composed of an innumerable assemblage of homogeneous crescent-shaped molecules, without any common margin. Its movements are of two kinds, that of the molecules among themselves, and that of the whole revolving mass. It occurs in marshy places in the early spring. Plate XLII. fig. 6.

Sp. 6. *Volvox globator.*—Commonly called the globe-animal. Spherical, membranous, the internal globules distant or scattered. Abundant in the infusions of hemp and tremella, and in stagnant pools during spring and summer. The following is an account of it by Mr Baker. "There is no appearance of either head, tail, or fins, and yet it moves in every direction, backwards, forwards, up or down, rolling over and over like a bowl, spinning horizontally like a top, or gliding along smoothly without turning itself at all; sometimes its motions are very slow, sometimes very swift; and, when it pleases, it can turn round as upon an axis very nimbly, without moving out of its place. The body is transparent, except where the circular spots are placed, which are probably its young." Another authority states that this species is at first very small, but increases to such a size that it may be discerned by the naked eye, and that its interior is filled with small globules, which are smaller animalcules, each of which contains within itself a still smaller generation, all perceptible by means of powerful glasses. The lesser globules may be seen escaping from the parent, and increasing in size.

Genus Proteus.—Body very small, simple, transparent, of varying form, changing itself instantaneously into different lobated shapes.

This genus is more obviously contractile than the preceding. It is seldom seen above a minute under the same form, but is continually passing from a simple oval or oblong to an irregular or sinuated shape, and *vice versa*. A species described by Roësel is so remarkable for this faculty, that it has been compared to a drop of water thrown upon oil. Hence also the generic name.

Sp. 1. *Proteus diffluens*.—Body diverging into branches. Occurs in the water of marshes. Plate XLII. fig. 7, 8, and 9.

Sp. 2. *Proteus tenax*.—Body prolonged to a fine point. Occurs in rivers and in sea-water. There are only two species described as belonging to this genus.

Genus Enchelis.—Body very small, simple, oblong, cylindrical, slightly variable.

There is a marked analogy between this genus and the following. The Enchelides are, however, short and thick compared with the Vibriones, which are slender and lengthened. To the genus now under consideration belong those animals which, if the recorded observations on the subject have been accurately made and faithfully reported, more than any other confound our preconceived ideas regarding the distinction between animal and vegetable life. The species alluded to are named *Zoocarpes* by M. Bory de St Vincent, or animated seeds, which appear reciprocally to give rise to and proceed from certain aquatic plants of the confervæ kind. They are formed in a bulbous-shaped part or swelling of the plant, are ejected when ripe, swim about for some time with a voluntary motion, throw out a root and a branch, become genuine vegetables, produce living seeds, and give birth to animals which, after a similar change of form, speedily return again to the vegetable state. These facts are vouched for by M. Bory de St Vincent, and are credited and confirmed by M. Dutrochet and several other continental inquirers, some of whom declare that they kept so watchful an eye upon the same individual as never to lose sight of it for a moment till they had witnessed the singular transformation above mentioned. We recommend it to our readers' consideration.

Sp. 1. *Enchelis viridis*.—Subcylindrical, obliquely truncated anteriorly. This species has an obtuse tail or terminal part. It continually varies its motion, turning from right to left. Occurs in long-kept water.

Sp. 2. *Enchelis punctifera*.—Subcylindrical, green, obtuse anteriorly, pointed posteriorly. This species is opaque, with a small pellucid spot in the fore part, in which two black points are seen, and a kind of double band crosses the middle of the body. It occurs in marshes. Plate XLII. fig. 10, 11.

Sp. 3. *Enchelis pulvisculus*.—This species bears a great resemblance to the *Monas pulvisculus* of Müller, which is the *E. monadina* of Bory de St Vincent. It is, however, double the size, deeper tinted, and more ovoid. It is found in the waters of marshes, and accumulates around the sides of jars or vases in which confervæ have been kept. It forms on the surface of water a slight pellicle of a delicate green colour, which is supposed to have been erroneously regarded by many botanists as a vegetable production, and described under the name of *Byssus flos aquæ*. On dying it becomes more lengthened and pellucid, or at least retains only a slight central spot of green. Plate XLII. fig. 12.

Sp. 4. *Enchelis amœna*.—This is a new species, of a lively green colour, discovered by Bory de St Vincent. In swimming it appears to elongate itself, and advances with the more slender end foremost. Two individuals are sometimes observed to unite and form one animal, of a perfectly spherical form, and similar in aspect to a Volvox.

Sp. 5. *Enchelis tiresias*.—This species was also discovered by the above-named writer, and led to his peculiar views regarding those apparently animated seeds which he has named *Zoocarpes*. He asserts that he has seen this animalcule formed in the articulations of a true conferva; that it burst from its vegetable envelope with a gyration or circular movement; that it soon produced a translucent prolongation of its body, which may be called anterior, as it then swam in the direction of that new organ, which, with the body itself, became visibly longer, till the creature finally acquired the exact form of the *Enchelis deses* of Müller. The chief difference seemed to be that it always moved with the slender end foremost, whereas the species just mentioned swims with its blunt end in advance. It is described by recent French writers as an " animal extraordinaire qui n'est certainement que la grain vivante d'un végétal." (See *Dict. Class. d'Hist. Nat.* tome vi. p. 156.)

Sp. 6. *Enchelis deses*.—This species is of an obscure green, much elongated, and moves with the thick end anteriorly. " Celui-ci (the obtuse portion) paraît comme tronqué dans certains aspects; et en examinant attentivement cette sorte de troncature, on la réconnaît formée par un cercle en forme de disque moins foncé que le reste de l'animal. La pointe postérieure est parfaitement hyaline. Dans la pensée où nous sommes que les Enchelides vertes ne sont que des Zoocarpes, ou propagules animés de quelques genres d'Arthrodiées, nous croyons que le disque obscurément transparent de la partie antérieure n'est que la marque du point sur lequel doit se développer l'article par lequel doit s'allonger en filament confervoïde le Zoocarpe, lorsque, arrivé au terme de sa carrière animale, il doit se fixer et prendre racine par le point hyalin de la partie postérieure." (*Loc. cit.* p. 157.) We present the above passage to our readers without note or comment, as we do not ourselves understand the zoocarpal nature of an Enchelis.

Genus Vibrio.—Body very small, simple, cylindrical, elongated.

Animalcules have been described as constituents of this genus, which probably do not at all belong to it, being too complicated in their structure. If the *V. aceti*, for example, commonly called the vinegar eel, is furnished with a mouth, lips, and alimentary canal, it does not even pertain to the class Infusoria, however small its dimensions. But many of the species are undoubtedly of the simplest construction; and although they may present some appearance of an internal cavity or sac, they yet exhibit neither mouth nor other external orifice of any kind.

Sp. 1. *Vibrio lineola*.—Body linear, extremely minute. Occurs in many vegetable infusions in such numbers as apparently to occupy their entire space. It is so small, that with the best magnifiers little more can be discerned than an obscure tremulous motion. It is supposed to exceed even the *Monas termo* in tenuity. Plate XLII. fig. 13.

Sp. 2. *Vibrio spirillum*.—Filiform, and twisted spirally, which seems to be its natural shape, as it is never observed to unbend, but moves forwards with a vibratory motion at both ends. Found in an infusion of *Sonchus arvensis*. Plate XLII. fig. 14.

Sp. 3. *Vibrio vermiculus*.—Presents a milky aspect, with a blunt apex, and moves with a languid vermicular motion. It has been found in marshy water in November, but is seldom seen. It agrees with the animal mentioned by Leeuwenhoeck as occurring in the dung of frogs.

Sp. 4. *Vibrio paxillifer*.—" Animalculum," says Mül-

ler, "vel congeries animalculorum mirabilis. Pluries in guttulis aquæ marinæ vidi corpuscula linearia flavescentia (solitaria paleas, in quadrangula disposita scobes referebant), granulaque seminalia qualiscunque vegetabilis diu credidi; demum nocte inter 6 et 7 Octobrem 1781 aspectu fili flavescentis, sese in longum producentis et in breve contrahentis, ac ex his paxillis compositi, obstupefactus, novoque phænomeno gavisus, ejusdem variis evolutionibus incubui." A salt-water species, abundant in ulva latissima. Observed during the months of September and October. Plate XLII. fig. 15, 16, 17, 18, 19.

Sp. 5. *Vibrio serpens.*—Slender and gelatinous, with obtuse windings or flexures, resembling a serpentine line. It is rare, and occurs in river-water.

Section II.—Body Membranaceous.

Of scarcely perceptible thickness, whether flat or concave.

The organization of the animalcules of this section is scarcely less simple than that of the preceding; but their form, being in a small degree resistant, is less subject to variation from the pressure or other action of the surrounding fluids, which has been regarded as the proof of a certain progress or advance in the scale of structure.

Genus Gonium.—Body very small and simple, flattened, short, angular. Some species of this genus appear to be composed of several corpuscles united together under a common membrane. This appearance probably results from their cellular tissue, or from certain lines which are the rudiments of those spontaneous divisions formerly mentioned, by which their propagation is affected. Their movements are oscillatory.

Sp. 1. *Gonium pectorale.*—Quadrangular and pellucid, with sixteen globules of a greenish colour set in a quadrangular membrane, "like jewels in the breast-plate of the high-priest, reflecting light on both sides." Occurs in pure waters. Plate XLII. fig. 20.

Sp. 2. *Gonium pulvinatum.*—Quadrangular and opaque. Found in dunghills.

Sp. 3. *Gonium corrugatum.*—Sub-quadrangular, whitish, marked by a longitudinal line. This species is found in various infusions, particularly that of the pear.

Sp. 4. *Gonium truncatum.*—Internal molecules dark green. Anterior extremity forming a straight line, with which the sides produce an obtuse angle, terminated posteriorly by a curved line. This species exhibits a languid motion. It is much larger than the preceding, and occurs, though rarely, in pure water.

Genus Cyclidium.—Body very small and simple, transparent, flattened, orbicular or oval.

The motions of this genus are oscillatory, circulatory, or demi-circulatory, more or less interrupted, and languid or lively, according to the species.

Sp. 1. *Cyclidium bulla.*—Orbicular and hyaline. General appearance pale and pellucid, with the edges somewhat darker than the rest. It moves slowly in a semicircular direction, and occurs in the infusion of hay.

Sp. 2. *Cyclidium hyalinum.*—Oval, depressed, perfectly transparent, terminated by a tail-like elongation. This species is very common, and is produced in many infusions, particularly in those of the cerealia. It swims in a vacillating manner, and as if continually trembling. Plate XLII. fig. 21.

Sp. 3. *Cyclidium Nucleus.*—Of a brownish tinge, deeper behind, and shaped exactly like an apple pippin.

Genus Paramæcium.—Body very small, simple, transparent, membranous, oblong.

The species of this genus, according to Lamarck, scarcely differ from those of the preceding, except in their more lengthened forms and a slight increase of animal development. They appear to vary instantaneously according to their position in relation to the eye of the observer; but their real form is tolerably determinate. The mode of increasing the species by transverse and longitudinal divisions, or natural cuttings, is very obvious in this genus. They are nearly related to the following, but are less sinuous and irregular. Their movements are for the most part slow and indefinite. They swim horizontally on one of their flattened surfaces, after the manner of flounders.

Sp. 1. *Paramæcium aurelia.*—Body compressed, with a kind of plait or fold towards the apex, acute behind. Very common in water where confervæ grow. Plate XLII. fig. 22, 23, 24.

Sp. 2. *Paramæcium chrysalis.*—Plicated anteriorly, obtuse behind. Occurs during the autumn in sea-water.

Sp. 3. *Paramæcium versutum.*—Cylindrical, thickened posteriorly, obtuse at both ends. Found in ditches.

Genus Kolpoda.—Body very small, simple, flattened, oblong, sinuous, irregular, transparent.

This genus is nearly allied to the preceding, and differs from it chiefly in its more varied forms. It is also less subject to the influence of pressure by the medium in which it lives. An Italian naturalist of the name of Losana has lately published a monograph on Kolpoda; but his figures are somewhat exaggerated, and not very naturally expressed.

Sp. 1. *Kolpoda lamella.*—Elongated, membranaceous, curved anteriorly. This species is seldom met with. It has a singular vacillatory mode of movement, and advances on its sharp edge, instead of its flattened side, the more usual position.

Sp. 2. *Kolpoda gallinula.*—Oblong, the anterior portion of the back membranaceous and hyaline. In corrupted sea-water.

Sp. 3. *Kolpoda crassa.*—Yellow, thickish, somewhat opaque, curved a little in the centre, kidney-shaped. This species has a quick vacillatory motion, and becomes apparent in the infusion of hay generally in about 13 hours. When the water is nearly evaporated it assumes an oval form, becomes compressed, and bursts.

Sp. 4. *Kolpoda rostrum.*—Oblong, hooked anteriorly. The movements of this species are slow and horizontal. It is found, but not frequently, in water where the lemna grows.

Sp. 5. *Kolpoda cucullus.*—Ovate, ventricose, the top bent into a kind of beak, and an oblique incision beneath the apex. This species is found in vegetable infusions, and in fetid hay, and usually moves with great velocity. It is pellucid, and appears as if filled with little bright vesicles, which differ in size. Some have supposed them to be lesser animalcules which the Kolpoda has swallowed; but as it has no mouth wherewith to swallow, Müller is more probably right in regarding them in the light of germs. When about to die in consequence of evaporation, it protrudes its contents, whether food or offspring, with great violence. Plate XLIII. fig. 25, 26, 27, 28.

Genus Bursaria.—Body simple, membranaceous, concave.

This genus occurs in fresh, saline, and stagnant waters. It appears to vary its form beneath the eye of the observer, and, from a rounded flattened shape, assumes a concave or somewhat purse-shaped aspect.

Sp. 1. *Bursaria truncatella.*—Follicular, with a truncated apex. This species is visible to the naked eye. It moves from left to right, and from right to left; ascends to the surface in a straight line, and sometimes rolls about as it descends.

Sp. 2. *Bursaria bulina.*—Boat-shaped, labiated anteriorly. This species is pellucid and crystalline, with brilliant globules within it. It is concave on the upper side, and convex below.

Sp. 3. *Bursaria hirundella.*—With two small wing-like projections, which give it somewhat of the appearance of a bird. It is invisible to the naked eye, but appears under the microscope like a pellucid hollow membrane. Recent micrographical observers doubt if this species really pertains to the present genus. Plate XLIII. fig. 29.

Order II.—Appendiculated Infusoria.

Furnished exteriorly with projecting parts.

The animalcules of this second principal order or division, though still infinitely small, gelatinous, and transparent, are so far less simply organized than their predecessors, inasmuch as they are furnished with salient parts, such as hairs, horns, or tail-like appendages, or at least with such projecting organs as, for want of more appropriate terms, we are obliged to designate by those names. They multiply both by division and by the bursting forth of internal germs. Though their essential fluids, and the living tissue which contains them, are probably of a more compound nature than those of the naked Infusoria, they have not yet reached that point of organization in which special organs are developed for the performance of particular functions; and it is not till we reach the higher class of Polypi that these are distinctly perceptible.

"Il paraît," observes Lamarck, "par les nombreuses espèces déjà connues et publiées, que les Infusoires de cet ordre sont bien plus nombreux dans la nature que les Infusoires nus. Cela doit être ainsi d'après les principes que je me suis cru fondé à établir.

"En effet, dans les Infusoires nus, l'origine encore trop récente des races qui proviennent de celles, en petit nombre, qui furent générées spontanément, n'a permis à la durée de la vie et aux circonstances qui ont influé sur ces races, qu'une diversité peu considérable. Mais à mesure que la durée de la vie, que sa transmission dans les individus qui se sont succédés en se multipliant, et que les circonstances ont eu plus de temps pour exercer leurs influences, les races se sont diversifiées de plus en plus, et sont devenues plus nombreuses.

"Cet ordre des choses, qu'il est facile de reconnoître pour celui même de la nature, nous fait sentir pourquoi les *Infusoires* sont bien moins diversifiés et moins nombreux que les *Polypes.* Effectivement, quoique nous ne connaissions pas probablement tous les Infusoires, et que nous connaissions bien moins encore tous les Polypes, ce qui est déjà connu de part et d'autre indique que la diversité des Polypes est considérablement plus grande que des Infusoires. Aussi les Polypes sont plus éloignés de leur origine que les Infusoires." (*Animaux sans Vertèbres,* tome i. p. 433.)

The first genus of this order (*Trichoda*), as constituted by Müller, contains several species which manifest the rudiments of a mouth and the commencement of an alimentary canal: these, according to the negative characters of the class, do not belong to the Infusoria.

Genus Trichoda.—Body very small, transparent, diversiform, without caudal appendage, but garnished with soft hairs either on the whole or on part of its surface.

According to the views of Lamarck, this genus contains not only a great proportion of the genus *Trichoda* of Müller, but also the whole of the genus *Leucophra* of the Danish author. It is distinguished from *Kerona* by the want of the long, stiff, distant, corniform hairs which characterize the latter.

A. *Body ciliated over its entire surface.*

(Leucophra of Müller.)

Sp. 1. *Trichoda viridiscens.*—Greenish, cylindrical, opaque, thicker posteriorly. Found in sea-water.

Sp. 2. *Trichoda dilata.*—Body flattened, variable, with sinuated margins. Inhabits sea-water, and swims like a *Planaria.* It scarcely differs from the genus *Kolpoda,* except in being ciliated.

Sp. 3. *Trichoda scintillans.*—Of a green colour, oval, slender, and opaque. Occurs in stagnant water. A doubtful species, closely allied to *Volvox.*

Sp. 4. *Trichoda acuta.*—Ovate, with a sharpened point. Colour yellowish. Of this species the form is very variable. It occurs in sea-water among ulvæ. Plate XLIII. fig. 30, 31, 32.

Sp. 5. *Trichoda signata.*—Oblong, sub-depressed, with a blackish margin. Common in sea-water. This species is distinguished by a curved line in its centre, shaped like the letter *S,* one end of which sometimes assumes a spiral form.

Sp. 6. *Trichoda mammilla.*—Spherical, opaque, with an exsertile papilla. Occurs in the waters of marshes. It is of a dark colour, its short hairs are curved inwards, and it occasionally appears to project and draw in a little white protuberance.

B. *Body ciliated, or covered with short hair only over a part of its surface.*

(The greater proportion of the genus Trichoda of Müller.)

Sp. 7. *Trichoda grandinella.*—Spherical, pellucid, haired above. The minute ciliary appendages of this species are not easily discovered, as it seems to possess the power of withdrawing them at pleasure and instantaneously. It occurs both in pure water and that of infusions.

Sp. 8. *Trichoda cometa.*—Spherical, ciliated anteriorly, with one or more globular appendages behind. Found in pure water in the autumnal season. Plate XLIII. fig. 33, 34.

Sp. 9. *Trichoda solaris.*—Spherical and crystalline, its edges beset with diverging rays, which exceed in length the diameter of the body. This animalcule contracts and dilates, but is stationary in the same spot. In marine infusions. Plate XLIII. fig. 35.

Sp. 10. *Trichoda pubes.*—Oval oblong, gibbous, depressed anteriorly. The apex of this species is furnished with hairs, which are seldom visible till it is about to expire, when it protrudes and extends them vehemently, as if in a vain attempt to secure and detain a remaining particle of water.

Sp. 11. *Trichoda proteus.*—Oval, obtuse behind, with an elongated retractile neck. Apex haired. This species, according to Müller and Lamarck, is found in river water. It appears, however, to agree in general character and appearance with the *Proteus* described by Mr Baker, which usually occurs in the slimy matter adhering to the sides of vessels in which either animal or vegetable substances have been some time kept. That of which an account is given by Mr Adams was found in the slime produced by water containing small fishes, snails, &c. The body was something similar to that of a snail, but pointed at one end, while from the other proceeded a long, slender, "and finely proportioned neck, of a size suitable to the rest of the animal." If we credit Mr Baker, this animalcule, though its eyes are not discernible, plainly demonstrates by its actions that it can see; for though multitudes swim about in the same water, and its own progressive motion is

very swift, it never strikes against its neighbours, but directs its course with a dexterity "wholly unaccountable should we suppose it destitute of sight." Its entire shape bears a resemblance to that of a swan. See Plate XLIII. fig. 36 and 37. When alarmed, it draws in its supposed neck, becomes more opaque, and moves about slowly with the large end foremost. See fig. 38. After continuing for some time under this form, it will put forth a kind of wheel machinery, the motions of which are alleged to draw a current of water towards it from a considerable distance. After frequently pushing out and pulling in this shorter head, sometimes with and sometimes without the wheel-work, it will remain motionless, as if wearied or worn out; and then its long head and neck or apex will be again slowly protruded, after which it generally resumes its accustomed agility.

Genus Kerona.—Body very small, diversiform, without tail-like prolongation, and furnished with scattered, stiff, corniform hairs on some parts of its body.

To this genus Lamarck has united the Himantopus of Müller. The species are rare. They seldom occur in infusions, and are most frequent in the purer kinds of fresh and salt waters.

Sp. 1. *Kerona rostellum.*—Orbicular and membranaceous; one side angulated, the other furnished with a series of triple horns. Inhabits sea and river water. This species is alleged by Bory de St Vincent to be entirely destitute of hairs and cirri, and he therefore proposes to remove it to the order *Gymnodes*, which corresponds with our first order, the naked Infusoria. It is sometimes difficult to identify species in this department, or to ascertain, in a doubtful or contested case, that the same animalcule has been the subject of observation by two or more disputants. Plate XLIII. fig. 39.

Sp. 2. *Kerona cypris.*—Somewhat pear-shaped, compressed, the front furnished with hairs or vibrating points, inserted beneath the edge, shorter behind, and partly extended straight forward, partly bent downwards. Motion retrograde. Inhabits fresh water.

Sp. 3. *Kerona ludia.*—Smooth, pellucid, full of small points, the fore part clubbed and a little bent, the hinder part narrow; the base obliquely truncated, and terminating in a tail stretched out transversely. The top of that part which may be called the head, and the centre of the back, are furnished with long hairs. When this animalcule is at rest, its tail is curled; when in motion it is drawn tight and extended upwards. The movements of this species are lively and diverting.

Genus Cercaria.—Body very small, transparent, diversiform, furnished with a distinct but very simple tail.

This genus, as constituted by Müller, contains many species which bear no natural relation to each other; but his characters are precise and definite, and strictly applicable to those species which now form the genus as limited by modern observers. They occur more rarely among animal and vegetable infusions than in running streams and the waters of marshes. Their movements are for the most part circular and very rapid. With the exception of a well-marked tail, their organization is in every other respect extremely simple. If a mouth and the rudiment of a stomach or alimentary canal exist in any of these animals, such characters would remove them not only from the genus Cercaria, but from the class Infusoria, as defined at the commencement of this treatise. *A fortiori*, the existence of eyes (a fact assumed by some inaccurate observers) in any of the animalcular species, would entirely alter their position and arrangement in the animal kingdom. We cannot do better than report the observations of the venerable Lamarck (himself unfortunately now deprived of sight) on this obscure subject:—"Ici, comme dans le genre suivant, l'on est exposé, d'après la petitesse extrême des individus, à rapporter à la classe des Infusoires des animaux qui, par leur organisation, appartiennent à d'autres points de l'échelle animale."

"Une bouche, quoique d'abord inaperçue, et conséquemment l'ébauche d'un sac alimentaire, peuvent exister dans certains de ces animaux, et dès-lors ils appartiennent au premier ordre des Polypes; mais des yeux, comme on en a supposé dans certains Cercaires, cela est impossible.

"Avant de dire que le fait lui-même vaut mieux que la raisonnement, il faut, 1*mo*, constater que les points que l'on a pris pour des yeux, en sont réellement, et qu'ils ont chacun un nerf optique qui se rend à une masse médullaire, centre de rapports pour des sensations; 2*do*, il faut ensuite établir positivement que des animalcules réellement pourvus d'yeux, sont néanmoins, par leur organisation, de la même classe que les Infusoires." (*Animaux sans Vertèbres*, tome i. p. 444.)

This genus forms the nucleus of the new family of Infusoria proposed by M. Bory de St Vincent under the name of *Cercariées*, and which contains in all seven genera, the names and nature of which will be seen by referring to the tabular view. Müller, who was not practically acquainted with the spermatic animalcules, was attracted by the resemblance which some of the Cercariæ bore to the figures of those organic molecules in the works of his predecessors. He did not, however, assert their identity; and probably perceived that, although in their general aspect and mode of movement they resembled each other, their peculiar and very different localities, and even the details of their structure, rendered it advisable that they should be assigned to separate genera.[1]

Sp. 1. *Cercaria inquieta.*—Changeable, convex, with a slender tail. This species occurs in salt water, and is remarkable for assuming a variety of different forms. It is sometimes oval, sometimes cylindrical, sometimes shaped like a sphere. Plate XLIII. fig. 40.

Sp. 2. *Cercaria gyrinus.*—Body of a rounded form, with an acuminated tail. In swimming, this animalcule moves its tail like a tadpole.

Sp. 3. *Cercaria lemna.*—Changeable, sub-depressed, with an annulated tail. The C. lemna varies the form of its body in a manner almost as singular as that exhibited by the *Proteus*, already described. The body is triangular, or oblong, or kidney-shaped. Its tail is at times thick, short, annulated; at others it is long, cylindrical, and without rings; and when stretched out it sometimes vibrates with such velocity as to appear double. A small pellucid globule, which Müller regarded as the mouth, is perceptible near the apex; and there are also two excessively minute black points, which, whatever they may really be, are by some called eyes. It advances slowly by a few steps or movements at a time, and frequently shakes and bends its tail, in which position it bears a great resemblance to a

[1] The following are the characters of the genus *Zoosperma*, as recently established: "Corps non contractile, ovoïde, très-comprimé, avec une queue setiforme, aussi longue ou beaucoup plus longue, implantée à la partie postérieure, qui est peu ou point amincie. Ce genre, dont nous possédons un très-grand nombre d'espèces, se compose d'animaux spermatiques." (*Dict. Class. d'Hist. Nat.* tome iii. p. 356.) The production and existence of these animals, their nature and uses, are still among the many inscrutable mysteries of nature.

lemna leaf in miniature. This animalcule exhibits an advanced organization. Plate XLIII. fig. 41, 42, 43.

GENUS FURCOCERCA.—Body very small, transparent, rarely ciliated, furnished with a bipartite tail.

This terminal genus, according to the views of Lamarck, conducts us to the limits of the infusorial class, and we become thus more liable to deception in regard to the non-existence of a mouth than in the preceding genera. It is a dismemberment of the *Cercaria* of Müller, and probably contains many species which will be placed elsewhere when future and more continuous observation shall have thrown additional light upon their nature and attributes.

Sp. 1. *Furcocerca podura.*—Cylindrical, acuminated posteriorly. This species is pellucid, and seems to consist of a head, trunk, and tail, the first of which, in the view of some observers, "resembles that of a herring." It turns round as if upon an axis when it moves, and is usually found in the months of November and December, in places where the lemna abounds. The tail frequently, but not always, appears to be divided into two. One of Müller's figures of this species is probably erroneous. He represents it as covered with short hairs; whereas, to more recent observers, it appears perfectly smooth. Plate XLIII. fig. 44, 45.

Sp. 2. *Furcocerca viridis.*—Cylindrical, variable, divided and acuminated behind. Occurs in spring in ditches and standing pools. It frequently contracts its anterior and posterior portions, so as to assume a spherical form. It is difficult to determine the genus to which this species belongs. Lamarck is supposed to have erred in placing it where it now stands. In truth, the genus appears to have been rather established provisionally, than upon an assured and natural foundation. The varying forms of the species which it contains render it extremely difficult either to discern or describe them with precision. Plate XLIII. fig. 46, 47, 48.

We have now endeavoured to present a general view, and a systematic exposition, of the principal features of the animalcular world; and if our statements have been less explicit, and our arrangement less complete and methodical, than accords with the reader's expectation, these defects must in part be attributed to the uncertainty which still prevails regarding a subject of which many of the essential characters scarcely lie within the limits of human intelligence. The observations and experiments of the English microscopical observers of last century, though they might amuse the general student, are too vague and fanciful to be now regarded as parts of the assured history of animalcules. The ultra-analogical reasoning on subjects of natural science with which we have been lately favoured by such men as Oken and Geoffroy St Hilaire, are tame in comparison with the inferences deduced by some of our older observers, who describe with minuteness the head, eyes, mouth, jaws, throat, stomach, intestines, and other parts of animalcules, which the improved glasses of modern times do not reveal to the vision of not less patient inquirers. The recent observations on the motions of the pollen of plants, which have puzzled the modern philosophers, would have opposed but feeble barriers in the way of our predecessors. "To discover," says Buffon, "whether all the parts of animals, and all the seeds of plants, contained moving organic particles, I made infusions of the flesh of different animals, and of the seeds of more than twenty different species of vegetables; and after remaining some days in close glasses, I had the pleasure of seeing organic moving particles in all of them. In some they appeared sooner, in others later; some preserved their motions for months, and others soon lost it. Some at first produced large moving globules resembling animals, which changed their figure, split, and became gradually smaller; others produced only small globules, whose motions were extremely rapid; and others produced filaments, which grew longer, seemed to vegetate, and then swelled and poured forth torrents of moving globules." It was from these and similar observations that the theory arose proposed by Baron Munchausen (an ominous name!). The Baron perceiving that these moving globules, after taking a little exercise, began again to vegetate, drew the conclusion that they were first animals and then plants; thus anticipating by more than half a century the supposed discoveries of some modern physiologists. Which of them was first in error it is perhaps of little consequence to inquire; and we allude to the subject here rather in connection with some singular observations by Mr Ellis, recorded in the 59th volume of the *Philosophical Transactions,* than from its own intrinsic importance. His object was to overturn Munchausen's hypothesis, by showing that the supposed Zoocarpes were nothing more than "the seeds of that genus of fungi called *mucor* or *mouldiness,*" and that their motions were caused by the attacks of myriads of animalcules! "Having at the request of Dr Linnæus made several experiments on the infusion of mushrooms in water, in order to prove the theory of Baron Munchausen, that these seeds are first animals and then plants, it appeared evidently that the seeds were put in motion by very minute animalcules, which proceeded from the putrefaction of the mushroom: for by pecking at these seeds, which are reddish, light, round bodies, they moved them about with great agility in a variety of directions; while the little animals themselves were scarcely visible till the food they had eaten had discovered them. The satisfaction I received from clearing up this point led me into many other curious and interesting experiments. The ingenious Mr Needham supposes these little transparent ramified filaments, and jointed or coralloid bodies, which the microscope discovers to us on the surface of most animal and vegetable infusions when they become putrid, to be zoophytes, or branched animals; but to me they appear, after a careful scrutiny with the best glasses, to be of that genus of fungi called *mucor* or *mouldiness,* many of which Michellius has figured, and Linnæus has accurately described. Their vegetation is so amazingly quick, that they may be perceived in the microscope even to grow and feed under the eye of the observer. Mr Needham has pointed out to us a species that is very remarkable for its parts of fructification (See *Phil. Trans.* vol. xlv. tab. 5, fig. 3, *a,* A). This, he says, proceeds from an infusion of bruised wheat. I have seen the same species proceed from the body of a dead fly, which was become putrid by lying floating for some time in a glass of water where some flowers had been, in the month of August 1768. This species of mucor sends forth a mass of transparent filamentous roots; from whence arise hollow stems, that support little oblong oval seed-vessels, with a hole on the top of each. From these I could plainly see minute globular seeds issue forth in great abundance, with an elastic force, and turn about in the water as if they were animated. Continuing to view them with some attention, I could just discover that the putrid water which surrounded them was full of the minutest animalcula; and that these little creatures began to attack the seeds of the mucor for food, as I have observed before in the experiment on the seeds of the larger kind of fungi or mushrooms. This new motion continued the appearance of their being alive for some time longer; but soon after many of them arose to the surface of the water, remaining there without

motion; and a succession of them afterwards coming up, they united together in little thin masses, and floated to the edge of the water, remaining there quite inactive during the time of observation." In like manner, the movements of the jointed coralloid bodies which Mr Needham has named *chaplets* and *pearl necklaces* are attributed to the attacks of their animalcular enemies. "When a small portion of these branches and seeds are put into a drop of the same putrid water upon which the scum floats, many of these millions of little animalcula with which it abounds immediately seize them as food, and turn them about with a variety of motions, as in the experiments on the seeds of the common mushrooms, either singly, or two or three seeds connected together; answering exactly to Mr Needham's description, but evidently without any motion of their own, and consequently not animated!"

We shall conclude this subject with a short notice of another view of the matter, which has resulted from some recent experiments and observations by our celebrated botanist Robert Brown. While engaged in some inquiries regarding the structure of the pollen of plants, and its mode of action on the pistillum of phænogamous tribes, that accurate observer had occasion to immerse in water some particles taken from the full-grown anthers (previous to bursting) of *Clarkia pulchella*. Of these, he perceived by the microscope that many were evidently in motion, and that their motion consisted not only of a change of place in the fluid, but of a change of form in themselves; that is to say, a contraction or curvature about the middle of one side, accompanied by a corresponding enlargement or convexity on the other, frequently occurred. The particles were seen, in a few instances, to turn on their longer axis; and their general motions were of such a nature as to produce the conviction in Mr Brown's mind that they did not arise either from currents or evaporation of the fluid, but were proper to the particles themselves. Having ascertained that motion existed in the pollen of all the living plants which he examined, he next inquired whether, and for what length of time, this singular property was retained after the death of the plant. Specimens were experimented on, which had been dried and preserved in an herbarium for 100 years, and the moving molecules or small spherical bodies were still perceived in considerable numbers. "The very unexpected fact," says Mr Brown, "of seeming vitality retained by those minute particles so long after the death of the plant, would not perhaps have materially lessened my confidence in the supposed peculiarity; but I at the same time observed, that on bruising the ovula or seeds of Equisetum, which at first happened accidentally, I so greatly increased the number of moving particles, that the source of the added quantity could not be doubted. I found also, on bruising first the floral leaves of mosses, and then all other parts of those plants, that I readily obtained similar particles, not in equal quantity indeed, but equally in motion. My supposed test of the male organ was therefore necessarily abandoned. Reflecting on all the facts with which I had now become acquainted, I was disposed to believe that the minute spherical particles or molecules of apparently uniform size, first seen in the advanced state of the pollen of Onagrariæ, and most other phænogamous plants,—then in the antheræ of mosses, and on the surfaces of the bodies regarded as the stamina of Equisetum,—and, lastly, in bruised portions of other parts of the same plants,—were in reality the supposed constituent or elementary molecules of organic bodies, first so considered by Buffon and Needham, then by Wrisberg with greater precision, soon after and still more particularly by Müller, and very recently by Dr Milne Edwards, who has revived the doctrine, and supported it with much interesting detail. I now, therefore, expected to find these molecules in all organic bodies; and accordingly, on examining the various animal and vegetable tissues, whether living or dead, they were always found to exist; and merely by bruising these substances in water, I never failed to disengage the molecules in sufficient numbers to ascertain their apparent identity in size, form, and motion, with the smaller particles of the grains of the pollen. I examined also various products of organic bodies, particularly the gum raisins, and substances of vegetable origin, extending my inquiry even to pit-coal; and in all these bodies molecules were found in abundance. I remark here also, partly as a caution to those who may hereafter engage in the same inquiry, that the dust or soot deposited on all bodies in such quantity, especially in London, is entirely composed of these molecules. One of the substances examined was a specimen of fossil wood, found in Wiltshire oolite, in a state to burn with flame; and as I found these molecules abundantly and in motion in this specimen, I supposed that their existence, though in smaller quantity, might be ascertained in mineralized vegetable remains. With this view, a minute portion of silicified wood, which exhibited the structure of coniferæ, was bruised, and spherical particles, or molecules in all respects like those so frequently mentioned, were readily obtained from it; in such quantity, however, that the whole substance of the petrifaction seemed to be formed of them. But hence I inferred that these molecules were not limited to organic bodies, nor even to their products. To establish the correctness of the inference, and to ascertain to what extent the molecules existed in mineral bodies, became the next object of inquiry. The first substance examined was a minute fragment of window-glass, from which, when merely bruised on the stage of the microscope, I readily and copiously obtained molecules, agreeing in size, form, and motion, with those which I had already seen. I then proceeded to examine, and with similar results, such minerals as I either had at hand or could readily obtain, including several of the simple earths and metals, with many of their combinations. Rocks of all ages, including those in which organic remains have never been found, yielded the molecules in abundance. Their existence was ascertained in each of the constituent minerals of granite, a fragment of the sphinx being one of the specimens examined. To mention all the mineral substances in which I have found these molecules would be tedious; and I shall confine myself, in this summary, to an enumeration of a few of the most remarkable. These were both of aqueous and igneous origin, as travertine, stalactites, lava, obsidian, pumice, volcanic ashes, and meteorites from various localities. Of metals I may mention manganese, nickel, plumbago, bismuth, antimony, and arsenic. In a word, in every mineral which I could reduce to powder sufficiently fine to be temporarily suspended in water, I found these molecules more or less copiously; and in some cases, more particularly in siliceous crystals, the whole body submitted to examination appeared to be composed of them."

There were three points of importance which Mr Brown was anxious to ascertain regarding these molecules, viz. their form, whether they were of uniform size, and their absolute magnitude. He seems, however, not to have been entirely satisfied with his determination on any of these points. As to form, he states the molecules to be spherical. His manner of estimating the absolute magnitude and uniformity of size of the molecules found in the various bodies submitted to examination, was by placing them on a micrometer divided to five thousandths of an inch, the lines of which were very distinct; or, more rare-

Animalcule.

ly, on one divided to ten-thousandths, with fainter lines, not readily visible without the application of plumbago, as employed by Dr Wollaston, but which in this case was inadmissible. The results can only be regarded as approximate, but Mr Brown is disposed to believe that the molecule is of uniform size, though, as existing in various substances, and examined in circumstances more or less favourable, he regards it necessary to state that its diameter appeared to vary from $\frac{1}{15000}$th to $\frac{1}{20000}$th of an inch.[1]

Supplementary Observations.—1853.

Since the preceding exposition of animalcules was written, great and important additions have been made to our knowledge of the subject. Both the organic structure and the physiological functions of these creatures have been described at great length, and amply illustrated, by Ehrenberg of Berlin. We are deeply indebted to that author for much that he has achieved in an obscure and difficult department,—for his general views, not less than his detailed descriptions,—and especially for the influence which he has shown many animalcular beings to have exercised, by means of their siliceous remains, in the building up, as it were, of various geological formations. At the same time it must be borne in mind, that many of Ehrenberg's discoveries have been much contested, and that Dujardin and other recent writers do not accept his classification, in consequence of what they deem its hypothetical basis. In presenting the views of the first-named observer, we therefore do so under a sense of the critical correction which others have sought to bestow upon them, and of which we shall also in our present supplement endeavour to give a brief account.

The following is a summary of Ehrenberg's views of the general character and attributes of infusorial beings.

They are all organized,—the greater portion (probably all of them) highly organized bodies.

They constitute two very natural classes (Polygastrica and Rotatoria), according to their structure, and are further subdivisible upon the same principle.

Their existence in all quarters of the earth and sea, is proved; as is also that of individuals of the same species in the most opposite ends of the world.

Their geographical distribution upon the earth follows the laws observed as regulating that of other natural bodies.

Most of the Infusoria are invisible to the naked eye; many are just visible as moving points; the size of the body does not in any case exceed $\frac{1}{12}$th of an inch.

Invisible Infusoria, in consequence of their vastly aggregated numbers, colour large tracts of water with remarkable hues.

Though themselves invisible, they also give rise, in consequence of this aggregation, to a certain kind of marine phosphorescence.

They sometimes compose, though singly invisible, a kind of mould, very obvious in consequence of the multitudinous mass. In a single cubic inch of this mould, there may be above 41,000 millions of animalcules; and they probably constitute the chief proportion of living bodies on the face of the earth.

They are the most reproductive of all organized beings; and from one of their known modes of propagation, that of self-division, ensues a continual destruction of the individual, and yet a similar interminable preservation and extension of it, in air and water, bordering, it may be almost said, upon eternal life and growth.

The copulation of gemmæ, which perhaps includes the hitherto unsolved poly-embryonate riddle of the seeds of all plants and vegetable formations, is solved in the animalcular family of Closterina.[2]

They form in the course of time, in consequence of the enduring nature of their siliceous shells, indestructible earths, stones, and rocky masses.

With lime and soda we can prepare glass and swimming bricks out of invisible animalcules; we can use them as flints, and probably prepare iron from them; we use *mountain meal*, which is composed of them, as food in hunger.

They are sometimes injurious, by causing the death of fish in ponds, deteriorating clear water, and causing boggy smells; but they do not, as some have supposed, give rise to malaria, plague, and other maladies.

They appear to be, as far as yet known, sleepless.

They partially break up in reproduction (egg-laying), and thereby passively undergo great alterations of form.

They form invisible intestinal beings in man and other animals, even if the Spermatozoa are excluded from among them. They are themselves infected by both external and internal parasites.

[1] The following summary from the pen of Mr Brown contains the renewed expression of that gentleman's opinion, matured by some recent experiments on the subject of active molecules. "That extremely minute particles of solid matter, whether obtained from organic or inorganic substances, when suspended in pure water or in some other aqueous fluids, exhibit motions for which I am unable to account, and which, from their irregularity and seeming independence, resemble in a remarkable degree the less rapid motions of some of the simplest animalcules of infusions. That the smallest moving particles observed, and which I have termed Active Molecules, appear to be spherical, or nearly so, and to be between $\frac{1}{20000}$th and $\frac{1}{30000}$th of an inch in diameter; and that other particles of considerably greater and various size, and either of similar or of very different figure, also present analogous motions in like circumstances. I have formerly stated my belief that these motions of the particles neither arose from currents in the fluid containing them, nor depended on that intestine motion which may be supposed to accompany its evaporation. These causes of motion, however, either singly or combined with others,—as the attractions and repulsions among the particles themselves, their unstable equilibrium in the fluid in which they are suspended, their hygrometrical or capillary action, and in some cases the disengagement of volatile matter, or of minute air-bubbles,—have been considered by several writers as sufficiently accounting for the appearances. Some of the alleged causes here stated, with others which I have considered it unnecessary to mention, are not likely to be overlooked, or to deceive observers of any experience in microscopical researches; and the insufficiency of those enumerated may, I think, be satisfactorily shown by means of a very simple experiment. This experiment consists in reducing the drop of water containing the particles to microscopic minuteness, and prolonging its existence by immersing it in a transparent fluid of inferior specific gravity, with which it is not miscible, and in which evaporation is extremely slow. If to almond oil, which is a fluid having these properties, a considerably smaller proportion of water, duly impregnated with particles, be added, and the two fluids shaken or triturated together, drops of water of various sizes, from $\frac{1}{50}$th to $\frac{1}{2000}$th of an inch in diameter, will be immediately produced. Of these, the most minute necessarily contain but few particles, and some may be occasionally observed with one particle only. In this manner minute drops, which, if exposed to the air, would be dissipated in less than a minute, may be retained for more than an hour. But in all the drops thus formed and protected, the motion of the particles takes place with undiminished activity, while the principal causes assigned for that motion, namely, evaporation and their mutual attraction and repulsion, are either materially reduced or absolutely null."

[2] Among other difficulties with which the student of this department will have to contend is the following,—that many species classed by Ehrenberg and others as animalcules, are considered by botanists as pertaining to their particular kingdom. Thus the Desmidiaceæ, a great component group of Ehrenberg's family Basillaria, are viewed by Professor Bailey of New York as belonging to the vegetable kingdom. Among ourselves, Dr Harvey, so noted for his knowledge of marine plants, classes both these and the Diatomaceæ, as suborders of the *Chlorospermeæ*, or green *Algæ*. Mr Ralfs, who has written so excellent a monograph on the "British Desmidieæ," likewise regards these as Algæ. It is indeed a vexed question as to the animal nature even of the Diatomaceæ, which, by means of genera such as *Melosira*, and others, seem closely connected with the confervoid Algæ.

Animalcule.

They possess comparatively a lengthened life.

As the pollen of pine trees falls yearly in the form of sulphur-rain, so do the much more minute animalcules appear (being elevated by means of watery vapour) floating alive in the atmosphere, and sometimes even mixed with dust.

They generally, like the more highly-organized bodies, maintain themselves pretty uniformly against all external influences. Although they sometimes consume strong poisons without immediate injury, they do not do so without an after effect.

The weight of invisible Infusoria, although light, is calculable, and the most gentle current of air or draught can play with their bodies as with the vapour of water.

The obvious and very rapid motion of Infusoria, is reducible as follows:—*Hydatina senta* moves 1-12th of an inch in 4 seconds; *Monas punctum*, the same in 48 seconds; while *Navicula gracilis* takes 6 minutes 24 seconds to go the same distance.

Linnæus said, *omnis calx e vermibus:* either to maintain or deny *omnis silex omne ferrumve vermibus* would now be unjust.

Direct observations on the theory of *generatio primativa* are wanting in necessary strictness. Those who profess to have seen the sudden origin of the minutest Infusoria from elementary substances, have quite overlooked the compound structure of these organic bodies.

The frequent and wonderful changes of form of many Infusoria no doubt have their limits, although the laws which govern them are still to be defined.

The power of infusorial organization is exhibited by the strong chewing apparatus, with teeth, which they possess, and their exhibition, also, of a complete mental activity.

The study of the Infusoria has led to a more distinct and conclusive notion of animal organization in general, and of the limits which circumscribe the animal form; from which all plants and minerals, which want the animal organic system, are strongly and distinctly separated.

It finally results from these inquiries, that experience shows an unfathomableness of organic creations, when attention is devoted to the smallest space, as it does of stars when directed to distances the most immense.

It was the prevailing opinion, till of later years, that the generality of animalcules were devoid of external organs; but the use of coloured substances, and the introduction of achromatic glasses have certainly shown a much more composite structure than was formerly known to exist. The simplest member is a delicate filament, placed near the oral orifice, and therefore called the *proboscis*. When the animalcule is in motion, this proboscis seems to act as a sort of oar or paddle, while, at the same time, by creating a current in the direction of the mouth, it aids in the prehension of food. *Cilia* are shortish hairs, placed apparently upon a bulb. They vibrate rapidly, the hair turning round upon something like an articulated surface, while the points describe a comparatively large circle. These cilia show themselves remarkably among the Rotatoria, in the shape of wheels, and both in form and action may be regarded as among the most interesting spectacles presented by the animalcular world. Naturalists are somewhat divided regarding their functions. Many look upon them as organs of respiration, and there is no doubt that corresponding parts are placed around the gills of many mollusca, and bring to them currents of fresh water for the purposes of breathing. Of the existence of *eyes* in the animalcular world we are still extremely doubtful, when we consider the fact of their non-existence in great groups distinguished in all other respects by a more complex and complicated organization. In Müller's great work no eyes are represented in any of the Polygastric species, but certain specks containing a red pigment have been assumed as eyes by Ehrenberg; and he argues that even if no other proof of the existence of a nervous system in these animated atoms could be adduced, the visual spots referred to would be sufficient to prove it. Having, as he supposes, discovered visual organs in these red specks of the Rotatorial families, he argues from analogy that the same parts perform similar functions in the Polygastric groups. M. Valenciennes maintains that in the Rotatoria these eye-specks are distinctly defined, have an investing capsule, and a crystalline lens, and consequently possess the essential attributes of organs of sight. On the other hand, owing to the extreme minuteness of the Polygastric species, all appearance of definite outline is wanting in their red specks, and as similar characters occur upon the reproductive germs of *Algæ* (which belong to the vegetable kingdom), their necessarily visual character is denied by many considerate observers.

"The sense of sight," says M. Dujardin, "would partake more of the character of a reality if the colour of a speck without appreciable organization, without a constant form, or a precise contour, sufficed to prove the existence of an eye. But in the genus *Euglena*, which is particularly cited as characterized by such an organ, the red spot so regarded is excessively variable, sometimes multiple, at other times made up of irregularly aggregated granules. Analogy, too, is inadequate to the solution of the question; for, on descending the animal series, to determine the nature of this coloured speck, we have to leap from the Daphniæ (an *Entomostracal* tribe) with a moveable eye, repeating in its composition that of Insects and Crustacea, to animals presenting nothing but diffused coloured specks.

"Such spots, whether in number or position, have so little physiological importance in the Planariæ, and in certain Annelides, that they are often not even to be employed as an absolute specific character. In the Rotatoria, the analogy with which is more especially insisted on, these pigment spots are, in some species, known to disappear from age, and in others to become more evident in proportion to size or development of individuals: so that the learned micrographer of Berlin, in his attempt to base the generic characters of these animals on the presence and number of eyes, has been led to place in different genera, species very closely allied, if not identical. Indeed, that a black or a red colour is in general an attribute of the pigment of eyes, cannot be a reason for concluding an eye to exist wherever we find such colours; if so, we must accord it to some intestinal worms, such as the *Scolex polymorphus*, which has two red spots on the neck, to the *Actiniæ*, which are often strewed with such specks, and also to some bivalved mollusks.

"If the ability of the Infusoria to direct their course through the liquid, and to pursue their prey, be appealed to in evidence, it is certainly, in the first place, necessary to verify the reality of this faculty, which I think equally fabulous with all related concerning the instincts of these animals. Indeed it would not even prove the red specks to be eyes, since the greatest number of Infusoria supposed to be endowed with such a faculty are in want of them; and those which do possess them do not exhibit that power in any higher degree of development."[1]

In the opinion of M. Morren, the red pigment specks of *Lagenella*, *Cryptoglena*, and *Trachelomonas*, cannot be eyes, because in the last-named genus the coloured pigment is capable of being distributed over the whole body, in which case, according to Ehrenberg's supposition, the creature itself would be converted into nothing but an eye.[2]

Professor Owen observes, in relation to the movements of Polygastric animalcules, that although they may be per-

[1] *Histoire des Infusoires.*

[2] *Mem. de l'Acad. de Bruxelles*, 1841, taf. 14.

Animalcule.

ceived to avoid obstacles in their way, and rarely jostle one another, it is yet difficult to detect any definite cause or object of their movements.[1] After carefully watching for signs of volition, that great observer came to the conclusion that those movements partook in general of the nature of respiratory acts, rather than of attempts to obtain food or avoid danger. They seemed automatic rather than voluntary, as if governed by stimuli within or without the body, not felt, but reflected upon contractile fibre, and are therefore motions which never tire. He thus explains the fact already indicated in our abstract of Ehrenberg's general views, namely, that at whatever period of the night we examine living Infusoria, we shall invariably find them as ceaselessly active as during the meridian splendour, and thus that animalcules never sleep.

The same unsettled state of opinion as regards the eyes, pervades our knowledge of other important parts of animalcular economy, and even the great basis (the assumed peculiarities of the digestive system) of Ehrenberg's classification being regarded as hypothetical, the classification itself has been by many rejected on that ground. According to the Berlin naturalist, the functions of digestion among the Polygastrica are effected by means of numerous internal vesicles or stomachs; while in the Rotatoria, as in the generality of higher animals, there is only one. While studying species of the former class, Ehrenberg observed a vesicle to fill with food, and then saw the particles pass into another cell, and so on until, the nutritive portions having been imbibed by each stomach in succession, the refuse was discharged by the animalcule. That many other naturalists have been unable to detect this process is perhaps no conclusive argument against it, as great experience, and the most steadfast and accurate observation, are necessary in microscopical pursuits. Few have been able to detect the tubular connection between these stomachic cells, which, however, must exist if Ehrenberg's views are well founded. He affirms that he has often seen it, and the passage is very distinctly shown upon his plates. Baron Gleichen regarded these vesicles as eggs, although he failed to witness their discharge; and the existence of eggs among the Polygastric tribes, is perhaps as much of an assumption as any other. So far back as 1781, he tried to make certain Infusoria eat carmine, and found on the ensuing day that several of them had red granules in their interior.[2] He concluded that they had swallowed the colouring matter, and more recent repetitions of similar experiments led to the formation of Ehrenberg's system. Professor F. T. Meyen refuses to admit the facts on which it is founded, not only because he has failed to see the intestinal communication between the stomachs, but has observed these supposed stomachs moving rapidly in the interior of the body of many species, after the manner of those granules which circulate in the joints of *Chara*. He has often seen *Vorticellæ* with many globules of indigo in their interior, always moving round a centre; from which he infers there could not be a communicating canal between the so-called stomachs with an oral orifice, and an extremity directed towards the mouth. In regard to the true nature of these vesicles, and balls of similar diameter, found in the bodies of Infusoria, Meyen is of opinion that the true Infusoria are themselves vesicular beings, the interior of which is filled with a mucous substance: the thickness of the membrane forming the vesicle is easily ascertainable in several species, and in many he has noticed in this membrane an obvious spiral structure, resembling that which exists among cellular vegetables. In the larger Infusoria, a cylindrical canal (the œsophagus) traverses obliquely the membrane which forms the animal. The lower extremity of this canal dilates, more or less, when the creature has taken food, until it attains the dimensions of the balls, which are so obvious in the interior of these Infusoria. The inner surface of this upper portion of the intestinal canal is provided with cilia, which turn round not only alimentary substances but foreign bodies, till they have assumed a spherical form. During the formation of this ball, the stomach, according to Meyen (who admits that the part in question must be distinguished by that name), has a free communication with the œsophagus; and by means of the ciliary apparatus found at its exterior, new alimentary substances are introduced into this canal, and pushed as far as the stomach. When the ball has acquired the dimensions of the stomach, it is expelled by its inner extremity, and pushed into the cavity of the body. It there forms an additional ball, if any solid substances had previously existed in the surrounding liquid. This second ball is itself pushed into the interior of the cavity of the animal, and drives before it the first ball along with the mucosities between the two—a successive formation of similar balls, by the food or other matter received into the animal, going on without interruption. Now, Meyen maintains that it is the simultaneous existence of many of these balls which has caused Ehrenberg to believe that these animalcules were *Polygastric*. To follow their formation, our observations must commence at the moment the animalcules are plunged into coloured liquid. The swallowing of the coloured particles takes place with great rapidity, frequently in half a minute, and the coloured balls may be seen one after another issuing from the stomach, and proceeding downwards along the internal wall of the cavity of the body. Their number is often so considerable as to fill the entire cavity, and they lie so close together as to form a large mass, which, as in the genus *Vorticella*, slowly turns upon itself. The vesicular cavities, according to Meyen, are not stomachs, and possess nothing in common with the balls, although the latter may get into them singly, but at the same time accidentally. The formation of these cavities, as well as their sudden and entire disappearance, may be traced as easily as the origin of the balls. It is even possible sometimes to see how one of these cavities moulds itself over a ball, and then disappears. The microscope reveals to us that they are not lined with a particular membrane, but are simply excavations of the pulpy substance. They often show themselves close to the inner surface of what forms the skin of the creature, and sometimes increase so greatly, that the diameter of even one is equal to the third or one-half of the entire cavity of the body.[3]

[1] *Comparative Anatomy and Physiology of the Invertebrated Animals*, p. 19.

[2] As the use of infusions is indispensable in the study of living microscopic objects, we extract the following notice of the method of feeding infusoria with coloured substances, from Mr Pritchard's work. Select for the purpose such coloured substances as are entirely free from metallic oxides, and not chemically soluble in water. They must, however, be capable of a very minute mechanical division. The substances generally used are carmine, indigo, and sap-green, the first being preferable. The material should be as pure as possible. Rub a piece of it once or twice on the stage glass, or what is better, the lower plate of an aquatic air-box, having first moistened it with a drop of water. The quantity of colour requisite is very small, no more than sufficient to render it appreciable by the naked eye; for if there be too much, the chances are that the particles will be too large for the creatures to imbibe. Having thus prepared the coloured food, place a drop of it beside a drop of water containing the animalcules, but not so near as that they may come in contact; then put gently on the cover of the air-box, and lower it sufficiently to flatten the two drops of fluid, but not to force them to unite. Now place the air-box under the microscope, and examine the animalcules closely, so as to ascertain that their stomachs are colourless; then press down the cover until the drops of fluid intermingle, which may be done under the microscope, and you will immediately perceive the creatures in great activity, and readily distinguish the cilia and proboscis of such as possess those parts, while in a few seconds their stomachs will be filled by the coloured substance.—See *Infusorial Animalcules*, p. 103. 2d Ed. 1852.

[3] *Edin. Phil. Jour.*, vol. xxviii.

According to Dujardin, the Infusoria (setting aside the *Systolides* or *Rotatoria*, as much higher in the animal scale, and also the *Bacillaria*, which, with *Closteria*, are more nearly related to the vegetable kingdom) derive their origin for the most part from obscure or unknown germs, in artificial and natural infusions, stagnant water, and rivers, or such portions of them as rest over vegetable remains; no other mode of propagation, except self-division, being well ascertained. Their fleshy substance is dilatable and contractile, like the muscular flesh of the higher animals, but it exhibits no absolute trace of fibres or membrane, seeming, on the contrary, to be homogeneous and diaphanous, except in cases where the surface appears articulated from contraction. This fleshy matter when isolated by tearing, or the death of the animalcule, shows itself in the liquid in the form of lenticular discs or globules, which refract light but slightly, and are capable of producing spontaneously in their substance spherical cavities analogous in appearance to the vesicles of the interior. In the living creature some of these vesicles are produced at the base of a sort of mouth, and are destined to contain the water swallowed with the aliments. They then pursue a certain course in the interior, and contract, and leave nothing in the centre of the fleshy substance, except the undigested particles. They can even discharge their contents externally by a fortuitous opening, which may be reproduced several times towards the same, though not the identical, point. The vesicles containing the aliment are independent, and neither communicate with an intestine, nor with each other, except in those cases where two vesicles incorporate. The other vesicles, which contain nothing but water, are formed much nearer the surface, and seem capable both to receive and expel their contents through the meshes of the integument. Spallanzani considered them as respiratory organs, and they may be so regarded, at least in so far as they multiply the points of contact of the interior substance with the circumambient fluid.

Dujardin is, moreover, of opinion in regard to the so-called eggs of Infusoria, their generative system, their organs of sense, their nerves and vessels, that none of these can be ascertained or determined with exactitude; and everything inclines him to believe that these minute creatures, although clearly endowed with a simple organization, according with their mode of life, cannot be regarded as possessing the same systems of organs as the higher tribes. The coloured points, for example, usually of a red colour, which have been regarded as eyes, cannot with propriety receive that appellation.[1]

Siebold is also opposed to the view that these vesicles or sacs are special and distinct digestive organs, and he denies the existence of any connecting canal. The *Astoma* (mouthless animalcules) he regards as nourished only by a general absorption of the surface. In the *Stomatoda* (those with evident mouths) he represents the oral orifice as continued into the interior by a sort of œsophagus, wide, and of very various form, terminating abruptly in the general loose parenchyma of the body. The food, when sought for, is drawn towards the mouth by the action of the surrounding cilia, and having been received into the mouth, enters the œsophagus, and is thence pushed onwards by a contraction of the part, in the form of a rounded globule, into the interior. After performing, during a sojourn there, a greater or less circuit, the food in the generality of *Stomatoda* is ejected through a fixed outlet, not, as Dujardin maintains, by means of a varying opening through the surface.

Wagner asserts that no one by any examination, however close, can convince himself of the actual existence of such an organization as Ehrenberg affirms. He maintains that in many Infusoria, where comparatively large bodies, such as *Naviculæ* or joints of *Algæ*, have been swallowed, no surrounding vesicle can be seen, and that these bodies will sometimes occupy the entire length and breadth of an animalcule. In the absence of mouth, nutrition seems carried on by the general surface. It may be safely inferred from these conflicting opinions that no settled or satisfactory conclusion can be formed, and that Ehrenberg's theory of polygastric structure, though it may be true, requires confirmation. The same may be said of several other organs and their functions. We have dwelt upon the digestive system at greater length than we shall do upon any other, as it forms the basis of Ehrenberg's arrangement of the animalcular kingdom.

In regard to the reproductive process among these infusorial tribes, *Monas vivipara* is regarded by Ehrenberg as the only species of the class that is viviparous. The formation of eggs is considered by that author as a fertile and frequent source of increase. Dujardin, again, views the viviparous attributes of the above-named Monas as more than doubtful, and the formation of ova in any infusorial species as by no means ascertained. He considers Ehrenberg's instances of oviposition as examples merely of *diffluence*, or the breaking up of the gelatinous substance of the animalcule into spherical atoms from want of moisture. With Siebold, he limits the reproductive process in this class to the two forms of gemmation and spontaneous fission. If this be true, then all that has been written of the ovaries, vesiculæ seminales, &c., falls to the ground. Professor Owen, however, is of opinion that the function of the nucleus of Infusoria in reproduction by spontaneous fission may be regarded as analogous to that of the essential contact of the Spermatozoon with the germ-cell in the development of the higher classes; and comparing the results in the two cases, he says it is certain "that the analogy between these phenomena in the multiplication of the parts of the germ-mass and those of the nucleus in the multiplication of monads is so close, that one cannot reasonably suppose that the nature and properties of the nucleus of the impregnated germ-cell, and that of the monad can be different." He therefore infers that the nucleus of the Polygastric animalcules is the seat of the spermatic power, though the term testes can only be figuratively applied; and he thinks that if Ehrenberg be correct in viewing the interstitial corpuscles as germ-cells, these essential parts of ova may receive the essential matter of the sperm from the nucleus, which is discharged along with them in the breaking up of the monad, which Ehrenberg regards as equivalent to an act of oviposition; and impregnated cells may thus, in Professor Owen's view, be prepared to diffuse through space, and carry the species of Polygastric animalcules to a distance from the scene of the life of the parent.[2]

Professor Weisse supposes himself to have detected reproduction by ova in *Chlorogonium euchlorum*, and maintains that the continuous observation of that species demonstrates that several of Ehrenberg's genera are nothing more than its natural development from stage to stage.[3] He describes the green matter of *chlorogonium* as developing, by spontaneous fission of itself, numerous young animalcules, which at first resemble *Uvella Bodo*, and are afterwards converted into *Chlorogonium euchlorum* and *Glenomorum tingens*. What he calls oviposition is the escape of the young by a transverse rupture of the parent, which is itself sacrificed, and disappears as a shrivelled sack. But in conformity with Thuret's views, it may be doubted whether the organic being (we shall not say creature) were really an animalcule, and not merely a thecaspore or zoospore (of an algæ), a production which so resembles the green-coloured Infusoria that Mr Pritchard states we have no means of dis-

[1] *Annales des Sciences*, 1840.
[2] *Essay on Parthenogenesis*, p. 67. Ed. 1849.
[3] *Archives für Naturgeschichte*, for 1846.

tinguishing between the two. It equally *produces* by the fission of its endochrome or green contents. M. Thuret has shown how close is the analogy between the reproductive bodies of *Confervæ* and those of the green animalcules. He regards the *Tetrasporæ*, although ranked with the *Algæ*, as of very doubtful vegetable nature. The movements of the animalcular genus *Diselmis* resemble those of zoospores, and the species equally turn to the light, under the influence of which, like algæ, they act upon the atmospheric air, disengaging a gas (oxygen?) when exposed to the rays of the sun. In a particular stage of one species, a very clear red spot was discernible, and a central globe closely resembling the amylaceous granules so common in the cells of algæ. It is the prevalence of the coloured speck in *Diselmis Dunalii* which, according to M. Joly, is the chief cause of the red colour so frequently observed over a large space of water in the Mediterranean Sea.

Whatever may be the special mode of generative increase among animalcules, their vast and rapid accumulation is as undoubted as extraordinary. Even among the Rotiferæ, direct observation has shown that a single individual will give rise to one million in ten days, and to sixteen millions in little more than a fortnight. If the children follow the footsteps of the parent, it is not easy to say what another fortnight might produce. Among the Polygastrica, the increase is still more speedy, one million having been produced from a single individual in seven days. Good and substantial food is, however, an essential condition of this rapid development; and when we consider what minute mouthfuls must suffice, we may the more easily conceive how rich a provender is spread before them in those innumerable infusions of animal and vegetable matters contained in almost all liquids. Fuchs has made some curious observations on the animalcules of cow's milk. He there finds in abundance two monadal species. He states that the blueness of milk is owing to the development and increase of an infusorial being, which he calls *Vibrio cyanogenus.* Under the name of *Vibrio xanthogenus* he defines another species, which he alleges makes milk turn yellow. Ehrenberg is of opinion that, in accordance with certain laws of nature, "living organisms," such as animalcules, may be developed in the air. The region of *atmospheric dust* is of vast extent, and ascends above 14,000 feet; and he conceives that its phenomena cannot be traced to mineral matters from the earth, nor to materials floating in space, nor to atmospheric currents, but rather bear relation to some general law of our atmosphere, in accordance with which there is a development within it of living organisms. The quantity of actual matter of this kind which falls from the air upon our earth is enormous, in consequence of the vast surface which it covers, however thinly. Meteorolites, although comparatively solid and massive, are as nothing compared with it. It has been calculated, that of atmospheric stones there fell, from 1790 to 1819, 600 cwt.; whereas a single dust-shower, which was deposited at Lyons in 1846, is estimated at 7200 cwt. As these showers have been numerous over the whole earth, Ehrenberg asks, how many millions of tons weight of animalcular beings have fallen since the time of Homer? Important results have been deduced from the examination of the animalcular dust which falls at sea, as well as on land, in the determination of the direction of atmospheric currents.[1]

Whatever defects may exist in Ehrenberg's system of arrangement, in consequence of some fallacies in his mode of viewing the organic structure and physiological functions of these extraordinary beings, there is no doubt that we owe to him many important observations and discoveries. He has especially pointed out the great influence exercised by these minutest of beings in the actual structure of the solid crust of the earth. He has satisfied both himself and others that the calcareous rocks of Syria and of Central North America contain densely crowded masses of small Polythalamiæ, several species of which, from the limestone of the New World, are identical with those of the European chalk. He has found the plastic marl of Ægina to consist of organisms, several of which pertain to the animalcules of the chalk. Lüneberg Heath is described as a great bed of Infusoria; and one of the largest deposits yet known is near Berlin, in which it is remarkable that species still living, but not hitherto discovered at the surface of the soil, are found among the fossil species. Quekett has recorded that an infusorial stratum, twenty feet in thickness, underlies the city of Richmond in Virginia, and that several of the forms agree specifically with those found in the North Sea. Abundance of microscopic shields belonging to marine Infusoria (both the siliceous-shelled Polygastrica, and the calcareous-shelled Polythalamia) occur in the deposits of the Elbe, near Hamburgh and Gluckstadt. Similar results were yielded by the mud of the Scheldt, and by marine deposits on the shores of the North Sea and Baltic. Ehrenberg has well shown the enormous proportionate extent and intensity of life in the highest latitudes both north and south, and at the greatest attainable depth of the ocean.

So prodigious are the aggregations of these smallest forms of life, that they have actually raised, and are still raising, vast tracts of land from the bottom of the sea. Our antarctic voyagers have informed us that the waters of the ocean, between the parallels of 60° and 80° south latitude, are of a pale ochrey-brown colour, in consequence of the enormous accumulation of these the frailest and yet least perishable parts of creation. Their death and decomposition have, we know not in the course of how long a period, actually produced a submarine bank or deposit of such vast dimensions, as to occupy an area of 400 miles long by 120 wide, flanking, as Dr Joseph Hooker has informed us, the entire length of the Victoria Reef.

Among the more singular localities of the Infusoria may be mentioned, not only meteoric dust, already noticed, but volcanic ashes, and other precipitations from the atmosphere. Ehrenberg has also shown that the blood-red spots which, to the terror of the superstitious, sometimes appear on bread and other substances, are occasioned by the surprisingly rapid development of an animalcule called *Monas prodigiosa.* He further supposes that one of the miracles in Egypt, recorded by the great lawgiver of the Jews, of the turning of water into blood, was produced, humanly speaking, by means of *Euglena sanguinea* (*Ascaria viridis* of Müller, for it is sometimes *green*), or by the use of another species called *Astasia hæmatodes.*

The character of the lorica, or somewhat shelly covering, differs in its nature and composition in the different genera; being in some entirely siliceous, in others, composed of lime, combined with carbonic acid as a carbonate, with a portion of the oxide of iron. As in many of the smaller genera it is difficult to ascertain whether they are enclosed in a lorica or not, we may here state Mr Pritchard's mode of ascertaining the existence of that character. Having obtained some specimens, say of the family *Cryptomonas,* he places a drop of water containing them in a compressor or crush-box, mixing a little colouring matter with the water. If the species are loricated, a clear transparent ring will be observed under the microscope, encircling the animalcules, and seeming to keep them separate from the fluid in which they are immersed.[2] Should this test prove unsatisfactory or insufficient, then the cover of the box may be pressed down, so as to

[1] A complete history of showers of meteoric dust will be found in Ehrenberg's *Passat-Staub und Blut-Regen,* of which a brief abstract is given in Pritchard's *Infusorial Animalcules,* p. 89.

[2] *Infusorial Animalcules,* p. 13.

Animalcule.

crush the specimens, when the coloured fluid will enter and surround their bodies; and, by a proper and expert management of the illumination of the microscope, the broken edges of the lorica will become visible.

The unfixed condition of opinion regarding infusorial animalcules is curiously indicated by the fact, that many careful and assiduous observers, such as Bauer, Leuckhart, Agassiz, and Reichenbach, deny the very existence of these creatures as a *class*, and maintain that they are mostly the embryonic forms of other and more highly organized beings. We doubt not that the opinion expressed in our preceding article, that our knowledge of this "invisible world" is in its infancy, is still correct, and that as the telescope brings forth stars from their nebular darkness, so the further the light of our microscopic knowledge penetrates into the obscure depth of the animalcular kingdom, the more clearly we shall have its now component parts resolved into definite forms of another nature than we at present suppose them. But that they are all merely embryonic forms, is doubtless a most visionary view, as no reason can be assigned *a priori* that beings, however small, are either uncertain or transitional, or that completion and finality of form are in any way inconsistent with excessive minuteness. One lesson may assuredly be drawn from the difficulties which beset the subject,—to avoid dogmatism, and bear in mind how unable we often are to solve the question, "What is truth?" But the extraordinary mutability of form and outward aspect of those frail creatures is no argument against their fixity of specific character within a certain range of variation, however wide. We know how different are the individuals even of some of the higher species from each other, under different circumstances, and at different stages of their life; but when once under our eye, they may be made cognizable to the senses of an observant person, under all their phases; that is, they may be identified with certainty from time to time. But with many animalcular beings it is not so. We see them once, as the astronomer may see some "bright particular star;" but we cannot calculate their erratic and changing course of life; and thus they may be either seen again no more for ever, or be observed under an altered aspect by another observer, and recorded with new characters under a different name. These, and such-like causes, may easily be conceived to operate disadvantageously against our speedy acquirement of assured knowledge regarding the animalcular tribes. But by means of patient and discriminating investigation on our own parts, a candid consideration of the observations of others, and an unbiassed record of whatever has been clearly ascertained, there is no reason why the subject should not be gradually advanced so as to take rank with other branches of a less ambiguous nature. The general reader will not wonder at the state of uncertainty which still pervades our notions of many animalcules, when we mention, as an example of extreme minuteness, *Monas crepusculum*, of which the number occupying the space of a grain of mustard seed, one-tenth of an inch in diameter, has been calculated at *eight millions!*

Ehrenberg's great group of polygastric animalcules is primarily divided into *Anentera* (such as do not possess a true alimentary canal), and *Enterodela* (or such as are furnished with an alimentary canal). Here we are met by a noted antagonistic observer upon the very threshold.

"Recent investigations," says M. Agassiz, "upon the so-called Anentera, have satisfactorily shown, in my opinion, and in that of most competent observers, that this type of Ehrenberg's *Polygastrica*, without gastric cavities, and without an alimentary tube, are really plants belonging to the order of algæ in the widest extension of this group; while most of the monad tribe are merely moveable germs of various kinds of other algæ. As for the Enterodela—most of them, far from being perfect animals, are only germs in an early stage of development. The family of *Vorticella* exhibits so close a relation with the Bryozoa (cilio-brachiate polypes), and especially with the genus *Pedicellina*, that I have no doubt, that wherever Bryozoa should be placed, *Vorticella* should follow, and be ranked in the same division with them. The terminal group of Infusoria, *Bursaria*, *Paramecium*, and the like, are, as I have satisfied myself by direct investigation, germs of fresh-water worms, some of which I have seen hatched from eggs of *Planaria* laid under my eyes."[1]

Not only are authors on our present department opposed to each other, but (a rarer case) they seem in some instances to have no great confidence even in themselves. Thus M. Dujardin, one of the most trustworthy of the modern microscopic observers, after giving in a tabular form the characters of the groups which constitute the family *Monadina*, sums up by stating: "But these generic distinctions are entirely artificial, and simply intended to facilitate the naming of Infusoria one may meet with in such and such infusions, and which, when better known, may prove in some instances to be but varieties of a single species."[2]

The preceding notices will suffice to show the still unsettled state of opinion regarding animalcules, and that Ehrenberg's system, although of great importance to the discriminating student, is not to be adopted implicitly as an assured exposition of the truth. We cannot here exhibit more of his arrangement than a compendious view of the family groups,—referring for details of genera and species to the work itself,[3] and to others, with a list of which we shall conclude these supplementary observations.

Tabular View of Ehrenberg's Arrangement.

					Family.
Anentera, without true Alimentary Canal.	No foot-like appendages. *Gymnica.*	Form of body constant.	Self-division complete.	illoricated, or without shell	Monadina.
				loricated, or shelled	Cryptomonadina.
			Self-division incomplete.	illoricated	Hydromorina.
				self-division general and globular	Volvocina.
				self-division unilateral (filiform) — illoricated	Vibrionia.
				self-division unilateral (filiform) — loricated	Closterina.
		Form of body variable.	illoricated		Astasiæa.
			loricated		Dinobryina.
	With variable foot-like processes. *Pseudopoda.*	illoricated			Amœbæa.
		loricated	Foot-like processes, compound		Arcellina.
			Foot-like processes, simple		Bacillaria.
	Hairy. *Epitricha.*	illoricated			Cyclidina.
		loricated			Peridinæa.

[1] *Annals of Natural History*, vol. vi. p. 156, 1850. Similar observations had been made by Mr Girard, who states that *Kolpoda cucullus* is an embryonic stage of a species of Planaria.

[2] *Hist. des Infusoires*, p. 273.

				Family.
ENTERODELA, with an Alimentary Canal.	One orifice. *Anopisthia.*	illoricated		VORTICELLINA.
		loricated		OPHRYDINA.
	Two opposite orifices. *Enantiotreta.*	illoricated		ENCHELIA.
		loricated		COLEPINA.
	Orifices situated obliquely. *Allotreta.*	illoricated	with proboscis, no tail	TRACHELINA.
			anterior mouth, a tail	OPHRYOCERCINA.
		loricated		ASPIDISCINA.
	Orifices abdominal. *Catotreta.*	illoricated	locomotive cilia	KOLPODEA.
			locomotive organs	OXYTRICHINA.
		loricated		EUPLOTA.

We shall conclude by observing that some years ago an idea became prevalent that animalcules might be *manufactured* by means of galvanism. The results of some of the experiments proved too much, for the creatures when examined were found to belong, not to the Infusorial tribes, but to the Arachnides, a class more highly organized than even Insects.[1] That the earlier naturalists, labouring under the disadvantage of imperfect glasses should have made mistakes is not surprising; but we read with wonder, in the year 1833, Dutrochet's statement that all the globular and elliptical Infusoria were merely vesicles set in motion by streams of electricity, and so might be artificially produced. In the following year Cagniard Latour declared that he had manufactured animalcules by means of carburetted hydrogen. But M. Audouin's examination proved that they were *Entomostraca*, and that the method employed in their production was fallacious. The following is Ehrenberg's account of some curious experiments on these imaginary productions by Professor Bondsdorff, communicated to the German Naturalists' Association in 1834. If a solution of chloride of aluminum be dropped into a solution of potassa, by the attenuate solution of the aluminum in the excess of alkali, an appearance will be given to the drop of aluminated matter, by the chemical changes and reactions which take place, as if the *Amœba diffluens* were actually present, both as to its form and evolutions, and it will *seem to be alive.* Such appearance, adds Bondsdorff, bears the same relationship to the real animalcule as a doll or figure moved by mechanism does to a living child.

The English reader will consult with advantage Mr Pritchard's *History of Infusorial Animalcules, living and fossil:* new edition, enlarged, Lond. 1852. A great mass of useful information is there collected, and Ehrenberg's system is given in detail. F. T. Kützing's *Die Bieselschaligen Bacillarien od. Diatomeen,* 1844, is an excellent work. Dujardin's has been already named in full, as perhaps the best systematic work we have on animalcules at the present time. Mr Ralfs' recent monograph on the *British Desmidieæ* (Lond. 1848) will be found indispensable; as also the Rev. William Smith's *Synopsis of the British Diatomaceæ,* vol. i. Lond. 1853.

The following is a list of papers published in the *Annals of Natural History,* from which much useful information will be gained:—On the existence of Infusoria in Plants; by Professor Morren; vol. vi. p. 344. On the Sacculi of Polygastrica; by Dr J. W. Griffiths; vol. xi. p. 438. On the production of Infusoria in the Stomachs of Herbivorous and Carnivorous Animals; by MM. Gruby and Delafond; vol. xiii. p. 154. On Microscopic Life in the Ocean; by Professor Ehrenberg; vol. xiv. p. 169. Abundant Occurrence of rare Infusoria in the Scallop; by H. Lee; vol. xv. p. 371. Microscopical Examination of the Chalk and Flint of the south-east of England; by Dr Mantell; vol. xvi. p. 73. On the Organization of the Polygastric Infusoria; by C. Eckhard; vol. xviii. p. 433. On Conjugation in the Diatomaceæ; by G. H. K. Thwaites; vol. xx. pp. 9 and 343. On the Siliceous Polycystina of Barbadoes; by Professor Ehrenberg; vol. xx. p. 115.

The following papers are from the new series of the *Annals:*—On the British Lagenæ; by W. C. Williamson; vol. i. p. 1. On the Diatomaceæ; by G. H. K. Thwaites; vol. i. p. 161. On a new British Species of Campylodiscus; by W. C. Williamson; vol. i. p. 321. Notes on Diatomaceæ; by Professor Dickie; vol. i. p. 322. On Fossil Diatomaceæ in Aberdeenshire; by Professor Dickie; vol. ii. p. 93. On a Diœcious Rotifier; by T. Brightwell; vol. ii. p. 153. On the colour of a Fresh-Water Loch; by Professor Dickie; vol. iii. p. 20. On the Mode of Growth in Oscillatoriæ; by J. Ralfs; vol. iii. p. 39. Observations on Recent Foraminifera; by W. Clark; vol. iii. p. 380. On two new species of Floscularia; by Dr W. M. Dobie; vol. iv. p. 233. On the Development of Trichodina pediculus; by J. T. Arlidge; vol. iv. p. 269. On the Conjugation of Closterium Ehrenbergii; by the Rev. W. Smith; vol. v. p. 1. On Deposits of Diatomaceous Earth on the shores of Lough Morne, county Antrim; by the Rev. W. Smith; vol. v. p. 121. On Nyctotherus, a new genus of Polygastrica; by Dr Leidy; vol. v. p. 156. On the Recent Foraminifera; by W. Clark; vol. v. p. 161. On the Nostochineæ; by J. Ralfs; vol. v. 321. On Asplanchna priodonta; by P. H. Gosse; vol. vi. p. 18. Notes on the Diatomaceæ, with descriptions of the British species included in the genera Campylodiscus, Surirella, and Cymatopleura; by the Rev. W. Smith; vol. vii. p. 1. On three new species of Animalcules; by J. Alder; vol. vii. p. 426. On the Germination of the Spore in the Conjugateæ; by the Rev. W. Smith; vol. viii. p. 302. On the Cell-Membrane of Diatomaceous Shells; by J. W. Bailey; vol. viii. p. 157. Remarks on Dickieia; by J. Ralfs; vol. vii. p. 204. Catalogue of the Rotifera found in Britain, with descriptions of five new genera, and thirty-two new species; by P. H. Gosse; vol. viii. p. 197. On Chantransia; by J. Ralfs; vol. viii. p. 302. Notes on the Diatomaceæ, with Descriptions of the British Species, included in the genus Pleurosigma; by the Rev. W. Smith; vol. ix. p. 1. (J. W.)

[1] For example, the animal obtained by Mr Crosse by means of galvanism was an *Acarus.* It was afterwards stated to be a well-known species, common in houses, and not unlikely to make its accidental way into a philosophical apparatus.

ANIMATION signifies the communication of life to an animal body. A fœtus was formerly said, in a legal sense, to be animated when it was perceived to stir in the womb; but this doctrine is exploded, animation being now dated from the moment of conception. See ABORTION.

ANIME, a resin exuding from the trunk of a large American tree, called by the Indians *courbaril* (a species of HYMENÆA). This resin is of a transparent amber colour, a light agreeable smell, and little or no taste. It dissolves entirely, but not very readily, in rectified spirit of wine; the impurities, which are very often in large quantity, remaining behind. The Brazilians are said to employ anime in fumigations for pains and aches proceeding from cold: with us, it is rarely, if ever, made use of for any medicinal purpose.

ANIMETTA, among *Ecclesiastical Writers*, denotes the cloth wherewith the cup of the eucharist is covered.

ANIO, or ANIEN, the modern TEVERONE, one of the most considerable tributaries of the Tiber, rises in the Apennines, about three miles above Trevi; and flowing first in a north-western, and afterwards in a south-western direction, joins the Tiber three miles above Rome. In its course it receives several small rivulets, among which is the Digentia of Horace, now the Licenza; and at Tibur it forms a beautiful cascade, originally the work of the Romans. The waters of the cascade are now carried through a tunnel constructed in 1834. Rome was supplied from this river, on account of the purity of its water, by means of two aqueducts, called the *Anio vetus* and *Anio novus*.

ANISE, an umbelliferous plant of the Linnæan genus *Pimpinella*. The seed is a very agreeable aromatic, and is much used in the confectionary art, in perfumery, and in medicine. It is a product of China, Egypt, and some other countries, and is cultivated in Germany, Spain, and Malta. The best comes from Alicante in Spain.

ANISO (from ἄνισος, *unequal*), a prefix to several terms in natural history, implying some kind or degree of inequality of parts: as, for example, *aniso-dactylous* birds, *i.e.*, having toes of unequal length; *aniso-dynamous* plants, *i.e.*, having flowers which grow with more vigour on one side of their axis than on the other; *aniso-stemonous* flowers, *i. e.*, having a greater or a less number of stamens than there are sepals in the calyx.

ANJAR, a fortified town of Hindustan, and the capital of a district of the same name in the native state of Cutch. The country is dry and sandy, and depends entirely on irrigation by means of wells. The town is situate nearly ten miles from the Gulf of Cutch. It suffered severely from an earthquake in 1819, which destroyed a large number of houses and occasioned the loss of several lives. One half of the town situated on low rocky ridges suffered comparatively nothing. In 1820 the population was estimated at 10,000.

The town and district of Anjar were both ceded to the British in 1816, but in 1822 they were again transferred to the Cutch government in consideration of an annual money payment. Subsequently it was discovered that this obligation pressed heavily upon the resources of the state, and in 1832 the pecuniary equivalent for Anjar, both prospectively and inclusive of the arrears which had accrued to that date, were wholly remitted by the British government. Lat. 23. 6. Long. 70. 3. (E. T.)

ANJENGO, a small seaport town and fortress of Hindustan, in Travancore, nearly encircled by a deep and broad river, at the mouth of which it is situated. The fort was built by the English in 1684, and it was retained till 1813, when the factory was abolished on account of the useless expense attending it. Anjengo is infested with snakes, scorpions, and centipedes; those animals finding shelter in the matted leaves of the cocoa-tree, with which the houses are mostly thatched. Here and at Cochin are manufactured, of the fibres of the Laccadive cocoa-nut, the best coir cables on the Malabar coast. The exports are pepper, coarse piece goods, coir, and some drugs.

ANJOU, a province and duchy of France before the Revolution, bounded on the east by Touraine, on the south by Poitou, on the west by Bretagne, and on the north by Maine. It now forms the department of Maine and Loire, and parts of Sarthe, Mayenne, and Indre and Loire. It is 90 miles in length, and 60 in breadth. Through this province runs the Loire, which divides it into two parts. Angers was its capital.

ANKER, a liquid measure at Amsterdam. It contains about $8\frac{1}{2}$ English imperial gallons.

ANKLAM, a circle in the government of Stettin in the Prussian province of Pomerania. It extends over 192 geographical square miles, and contains one city and 54 villages. In 1849 the number of inhabitants was 28,507. The land is level, with extensive woods, and about twenty fresh-water lakes, the largest of which is Ahlbeckr. The feeding of cattle and growing of corn are the chief objects of agriculture; besides which some hops and tobacco, and much flax, are grown The woods afford much profitable employment, and furnish charcoal to the iron-works in Pomerania. The capital of the circle is of the same name. It is situated on the river Peene, and is now without fortifications. In 1849 it contained three churches, three hospitals, 725 houses, and 9111 inhabitants. By means of the river it carries on some trade; and it has manufactures of cloth, hosiery, tobacco, snuff, and leather. Long. 13. 35. E. Lat. 53. 47. N.

ANKOBAR, or ANKOBER, the capital of the new kingdom of Shoa, in the province of Efat, and southern part of Abyssinia, Lat. 9. 34. 33. N. and Long. 39. 53. E., 372 miles travelling distance south-west from the seaport of Tajarrah, and 300 south-east of Gondar. It is built on the sloping side of a mountain 8200 feet above the level of the sea, and surrounded by an Alpine country. Pop. about 5000.

ANN, or ANNAT, in *Scottish Law*, is half a year's stipend which the act 1672, c. 13, gives to the executors of ministers of the Church of Scotland, over and above what was due to the minister himself for his incumbency. As it is a mere gratuity given by the law to those whom, it is presumed, the deceased could not sufficiently provide for, so it is neither assignable by him during his life, nor attachable by his creditors after his death.

Annats is applied in English law to the annual income of an ecclesiastical living, the first fruits paid originally to the pope by the successor of a deceased bishop, abbot, or parish-clerk. At the time of the Reformation, they were vested in the king; but in Queen Anne's reign were restored to the church, and appropriated to the augmentation of small livings.

ANNA, ANA, or ANAH, a town of Arabian Irak, or pachalic of Baghdad, which extends five or six miles along the western bank of the Euphrates. It consists of a single street built on both sides. The houses are of stone, two stories high, and separated from each other, as in other eastern towns, by beautiful gardens filled with fruit-trees, bearing lemons, oranges, citrons, quinces, figs, dates, pomegranates, and olives. It is an open and defenceless place, and in 1807 was plundered by the Wahabees, who massacred the greater part of the inhabitants, and set the town on fire; after which they retreated with their plunder, carrying into captivity many women and children. The inhabitants, previous to this calamity, are said to have been more polished than those in the neighbourhood, and to have consisted chiefly of Arabians, who were, however, addicted to their usual vocation of robbery when any opportunity presented. Pop. about 2000. 260 miles east of Damascus; 220 south-east of Aleppo. Long. 41. 47 E. Lat. 34. 10. N. It is the ancient *Hadith*.

ANNA *Comnena*, daughter of the Emperor Alexius Com-

nenus I., was not more distinguished by her elevated rank than by her mental qualifications. Her superiority of mind began early to display itself. Despising the effeminacy and voluptuousness of the court in which she was educated, she directed her attention to literary pursuits. Indulging her favourite studies, she solicited the acquaintance of the more eminent philosophers of that period.

But the pursuits of literature did not induce her entirely to abandon society; she gave her hand to Nicephorus Briennius, a young nobleman of a respectable family. This accomplished woman was, however, actuated by unjustifiable ambition; and during the last illness of her father, she united with the Empress Irene in attempting to prevail upon that monarch to disinherit his own son, and give the crown to her husband. The affection and virtue of the father prevailed over female address and intrigue. But the ambition of Comnena was not subdued. She entered into a conspiracy to depose her brother; and when her husband displayed timidity and hesitation in this unjust enterprise, she exclaimed that "nature had mistaken their sexes, for he ought to have been the woman."

Either through the vigilance of her brother or the timidity of her husband, the treasonable plot was discovered, and Anna punished with the confiscation of all her property. It was afterwards, however, restored to her by the generosity of her brother. Ashamed of her base conduct, she retired from court, and never more possessed any influence there. Disappointed ambition took shelter among the walks of literature, and she employed her solitude in writing the history of her father's reign. This production is still extant, and forms a part of the celebrated collection of the *Byzantine Historians*. The stores of rhetoric are ransacked to embellish this work, and every effort made to enrich it with science; but its general character is rather that of an apology than of an impartial narrative. It must, however, be acknowledged that she is not more partial than many other Latin historians, and that her history contains many valuable facts and observations. The best edition is by Schopen, 2 vols. 8vo.

ANNA *Ivanovna*, Empress of Russia, daughter of Ivan, brother of Peter the Great, was born in 1693, and married in 1710 to the Duke of Courland, who died the following year. After the death of Peter II., in 1730, the supreme council of the empire offered the vacant throne of Russia to Anna on the following conditions. She was to govern according to the decisions of the supreme council, and she was not allowed without its consent either to declare war or to conclude peace, to impose new taxes, to grant any important office of the state, to dispose of crown lands, to contract a matrimonial alliance, or to nominate a successor to the throne. She was also not to punish any noble, or to confiscate any one's property without a legal sentence. Anna signed these conditions without any opposition; but after her arrival at Moscow, a numerous party jealous of the authority which this constitution, imitated from that of Sweden, gave to the supreme council, or rather to the families of the Princes Dolgorouki and Galitzin, of whose members it was chiefly composed, petitioned the empress to assume the autocracy of her predecessors. Anna immediately complied with this request, and the framers of the constitution were either banished to Siberia, or perished on the scaffold. Russia was governed during the whole reign of Anna by her favourite Biren, who was made by her influence Duke of Courland, in a most tyrannical and oppressive manner, so that, according to Russian authorities, twenty thousand victims of Biren's tyranny perished during Anna's reign of six years; and amongst them persons belonging to the highest ranks in the country. The principal events of Anna's reign were the voluntary restoration, in 1732, to Shah Nadir of the Russian provinces, Shirvan, Ghilan, and Mazanderan, acquired by Peter the Great, but which caused more expense than they gave of revenue to Russia; a Chinese embassy at St Petersburg, the only one that was ever sent to Europe; the assistance given to the Elector of Saxony and King of Poland, Augustus III., against his competitor Stanislaus Leszczinski, supported by France; a Russian army sent to the assistance of the Emperor Charles VI. against France; a war with Turkey from 1736 to 1739, which, notwithstanding several successful campaigns, gave no advantage to Russia at the conclusion of peace; and an advance made into central Asia by the establishment of the Russian protectorate over the khan of the Kirguizes, who, with the assistance of Russian officers, conquered Khiva, but fortunately for our present interests in the East, did not maintain himself there.

Anna died in 1740. Her reign is considered as a period of transition from the old Muscovite semibarbarian manners to the polish though not the civilization of the West. (V. K.)

ANNA *Perenna*, an ancient Italian divinity, regarded as the giver of life, health, and plenty. In later times she was identified with Anna the sister of Dido, who threw herself into the Numicius, and was thenceforth worshipped as the nymph of that river. See Ovid. *Fast.* iii., Virg. *Æneid.* iv., Macrob. *Sat.* i. 12.

ANNABERG, a city on the mountains in the bailiwick of Wolkenstein, circle of Erzgebirge, and kingdom of Saxony. It is 1820 feet above the level of the sea, in the midst of a mining district, which yields silver, tin, and cobalt. In 1849 it contained 677 houses, and 9437 inhabitants, chiefly employed in manufacturing tapes, lace, sewing silk, besides many other articles. Lat. 50. 35. N. Long. 13. 0. E.

ANNAGH, an island about five miles in circumference, on the west coast of Ireland, between the isle of Achill and the mainland of the county of Mayo. Long. 9. 49. W. Lat. 53. 58. N. There is a small village of the same name in the county of Cork, five miles from Charleville.

ANNALS (*Annales*, from *annus* a *year*), a term commonly applied to a concise and plain kind of narrative of historical facts digested in the order of time, each event being arranged under the particular year in which it happened. Although this style of composition does not necessarily exclude the casual observations of the writer, episodes or formal digressions are incompatible with the brevity characteristic of annals: while history, on the other hand, comprises not only the narrative and exposition of facts, but also the writer's observations on actions, motives, causes, and consequences, in general; thus affording ample scope for illustration and embellishment. Annals may be said to constitute the essence of history, since they are the elements or materials of which it is composed.

We are told by Cicero (*de Oratore*, ii. 12), that from the earliest period of the Roman state the Pontifex Maximus, in order to preserve the memory of events, used to write down the public transactions of each year on a whited tablet, which he exposed in an open place at his house, that the people might come and read it; hence, in his time, these records were called *annales maximi*. The greater part of the annals composed by the Pontifex previous to the capture of Rome by the Gauls, perished at that time in the burning of the city, B.C. 390. These records, which appear to have been of a very meagre nature, were probably the same as the *Commentarii pontificum* cited by Livy. Commentarii was also used to denote the memoirs which an individual wrote concerning his own actions. Thus Julius Cæsar designated the celebrated account he wrote of his own campaigns with the unassuming title of Commentaries. It may be observed that this was a general term for any kind of notes or simple memoranda.

The practice of compiling annals was continued until the pontificate of P. Mucius Scævola and the time of the Gracchi, when its omission was a circumstance of less im-

portance, as a literature had been formed. After the pontifices ceased to compose annals, many other persons, both among the Greeks and the Romans, began to draw up historical accounts of public affairs, in which they imitated the condensed and unadorned style of the pontifical records. Cicero, in speaking of these annalists, says—"*unam dicendi laudem putant esse brevitatem.*"

The distinction, however, between annals and history properly so called, is a subject that has exercised the ingenuity of many distinguished critics, and given rise to more discussion than its intrinsic importance perhaps deserved. Aulus Gellius, in the *Noctes Atticæ* (v. 18), endeavours to demonstrate, on the authority of the grammarian Verrius Flaccus, that the derivation of the word history from ἱστορεῖν (*inspicere*, or *to inquire in person*), would seem to indicate that history is an account of events which happened during the time of the writer. Annals, again, he distinguishes as a relation of the events of earlier times, arranged under the respective years in which they occurred. Similar to this is the well-known definition given by Servius (*ad Æneid.* i. 373). This is the explanation that Gronovius has expressly declared to be satisfactory to himself; and it is the one which the learned Grotius has consented to follow in his *History of the Netherlands*, since he divides that great work into Annals and History accordingly. The *Historiæ* and the *Annales* of Tacitus would seem at first sight to countenance such a distinction, as the former work is occupied with the transactions of his own time, while the latter is devoted to the events of an earlier period. But, on the other hand, it is by no means certain that Tacitus made any such distinction between them; and it is more probable that he gave the title of *Annales* to both these works, if, indeed, he used either of the terms. It seems by no means improbable that the title of *Annales* was given to that work after the time of Tacitus; and, indeed, there seems to be no peculiar propriety in the designation simply because the events are arranged in the order of time, since that would render it equally applicable to the books of Livy, or Cæsar's Commentaries. The concise vigorous style of the *Annales* may have been one cause of their receiving that title; yet brevity was inseparable from the style of Tacitus, a peculiarity conspicuous even in the *Historiæ*; and in reference to which Montesquieu has remarked—"Tacitus knew everything, and therefore abridged everything." In the so-called *Annales* (iii. 65, iv. 71), Tacitus explains that he was prevented by the plan of the work from entering upon details in general, or anticipating the order of events; and this has given the *Annales* a greater degree of brevity than appears in the *Historiæ*. With respect to these titles, however, there is no direct evidence to prove that such a distinction as that mentioned by Aulus Gellius and Servius was recognised by writers contemporary with Tacitus, and it may fairly be presumed to have been the invention of a later period.

If Tacitus really gave no definitive title to either of the works in question, such omission, perhaps, was not without precedent. Niebuhr, in his ingenious but somewhat fanciful disquisition on the Distinction between Annals and History, concludes his remarks by the inquiry whether the title *Historiarum ab urbe condita* was the original designation of the books of Livy; and he conjectures that the historian may possibly have used neither *historiæ* nor *annales*, since Diomedes, Priscian, and other grammarians never cite otherwise than *Livius ab urbe condita libro*;—and he suggests that the strangeness of the inscription may have occasioned the filling up of the blank.—(See *Cambridge Philological Museum*, No. vi. 1833, p. 670; translated from the *Rheinisches Museum.*)

The high antiquity of the annalistic form of writing requires no demonstration; and perhaps there are few nations that possess no such memorials of their early history. The Chinese, whose veracity in matters of antiquity is frequently questionable, affirm that their annals date from so remote a period as 3000 years or more before the Christian era.

Independently of the consideration that annals are the basis of all history, there is one point of view in which they must be regarded as possessing a high degree of political importance. Knowledge being confessedly the basis of constitutional liberty, veritable annals may be said to be a record of facts unperverted by the bias of the historian; by means of which the people are to be guided and instructed, in order that they may appreciate the advantages they already possess, and be led to maintain inviolate those rights for which their progenitors have toiled and suffered.

ANNAMABOE, an English factory and fort on the Gold Coast of Africa, in Lat. 5. 5. N. Long. 1. 15. W. In 1808 it was gallantly defended by twenty-four English soldiers against 15,000 Ashantees, who destroyed the negro town and butchered the inhabitants.

ANNAN, a royal burgh and parish of Scotland, in the county of Dumfries, on the river of the same name, about two miles above its junction with the Solway Firth. The river is crossed by an elegant bridge of three arches, built in 1824. It has a good harbour, and the highest tides rise 21 feet. In 1851 the population of the town amounted to 3426. The people are chiefly engaged in the coasting trade, ship-building, gingham-weaving, and the curing of bacon and hams for the Newcastle and London markets. A cotton spinning manufactory has been long established in the town, giving employment to between 80 and 100 persons of different ages. The salmon fishery, which in former years was very productive, has much fallen off. Among the public buildings is a handsome academy, built and endowed by the heritors and the town-council: it is conducted by a rector and two masters, and is in a very flourishing state. Annan unites with Dumfries, Kirkcudbright, Sanquhar, and Lochmaben, in sending a representative to parliament. The environs are very inviting; and few places are more beautiful than the river and its finely-wooded banks, for eight or ten miles above the town. It had formerly a castle, built by the Bruces after they became lords of Annandale. Distance from Dumfries 14 miles, from Edinburgh 79.

The River Annan, on which the town stands, rises in the Hartfell Mountain on the confines of the counties of Peebles and Dumfries, and flowing southward, falls into the Solway Firth after a course of 30 miles. It abounds with trout and salmon. The stewartry or district of Annandale, of which Lochmaben castle was the chief fortalice, is a fertile vale, 30 miles long and about 16 miles broad. From its vicinity to England, and the continual incursions and predatory wars of the borderers, the greater part of it was uncultivated and common; but since the beginning of the last century all these wastes and commons have been subdivided and brought into culture, and the country has assumed a new appearance, which may be ascribed not only to the division of the commons, but likewise to the improvement made on the roads.

Annandale formed a part of the Roman province of Valentia; and it abounds with Roman stations and antiquities. The Roman camps at Birrens in Middlebie, on the hill of Birrenswark, and at Torwood Muir in Dryfesdale, are still nearly entire, and their form is preserved; and the traces and remains of a military road are yet visible in different parts of the country. The ruins of the house or castle of Auchincass, in the neighbourhood of Moffat, once the seat of that potent baron Thomas Randolph, earl of Murray, lord of Annandale, and regent of Scotland during the minority of David II., cover above an acre of ground, and even now convey an idea of the plan and strength of the building. The ancient castle of Comlongan, formerly belonging to the Murrays, earls of Annandale, and now to the earl of Mansfield, is still in a tolerable state of preservation; but except

Annand || Anne.

this castle, and that of Hoddam, most of the other old fortalices and towers are now taken down or in ruins.

ANNAND, William, Dean of Edinburgh, the son of William Annand, minister of Ayr, was born at Ayr in 1633. Five years after, his father was obliged to quit Scotland with his family, on account of their adherence to the king and to the Episcopal form of church government. In 1651 young Annand was admitted a scholar in University College, Oxford; and in 1656, being then bachelor of arts, was appointed preacher at Weston on the Green, near Bicester in Oxfordshire. After he had taken the degree of master of arts, he was presented to the vicarage of Leighton-Buzzard in Bedfordshire, where he distinguished himself by his edifying manner of preaching. In 1662 he went to Scotland as chaplain to John Earl of Middleton, the king's high commissioner to the parliament of that kingdom. In the end of the year 1663 he was instituted to the Tolbooth Church at Edinburgh, and from thence was removed, some years after, to the Tron Church of that city. In April 1676 he was nominated by the king to the Deanery of Edinburgh; and in 1685 he was made doctor of divinity in the university of St Andrew. He wrote several books on religious and ecclesiastical subjects. He died on the 13th of June 1689, and was interred in the Greyfriars Church, Edinburgh.

ANNAPOLIS, the capital of Maryland, in North America. It stands on the River Severn, two miles from its entrance into Chesapeake Bay, and is a small but well-built town, with a handsome state-house, &c. Population in 1850, 4198. Lat. 38. 58. 35. N. Long. 76. 33. W.

Annapolis, a county and town of Nova Scotia, on the Bay of Fundy. The town was the first French settlement in that part of the world; but was finally captured by the English in 1710, and ceded to them at the peace of 1713. The town is in Lat. 44. 40. N. Long. 65. 37. W. It is neither populous nor flourishing, but falling into decay. The harbour, however, is good.

ANNE, Queen of Great Britain and Ireland, was born on the 6th of February 1664. She was the second daughter of James Duke of York, afterwards James II. She was only seven years old when her mother, Anne Hyde, died, having previously professed adherence to the Church of Rome, a step which was immediately imitated by her husband. The Duke, however, had to allow his daughters, the princesses Mary and Anne, to be brought up as Protestants; and Anne always continued to be attached, zealously and even bigotedly, to the Church of England. In her twentieth year she was married to Prince George, the brother of the King of Denmark. In the establishment then formed for her, a place was given, on her own earnest desire, to her early playfellow Lady Churchill, afterwards Duchess of Marlborough; and this ambitious and imperious woman, acquiring rapidly an irresistible authority over the feeble mind of the princess, thenceforth ruled her absolutely for more than twenty years. Not long afterwards, when the Duke of York had become king, he made repeated attempts to convert the princess Anne to his own creed: he engaged that, if she would become a Roman Catholic, she should be placed in the line of succession to the throne before her elder sister Mary. Prince George appears to have received those overtures favourably; but he, an indolent and good-natured man, who cared for nothing but good eating and field-sports, never had any influence over his wife. She remained firm in her Protestantism, lived in retirement during the whole of her father's reign, and did not allow her opinions or feelings any further vent than that which they found in her private correspondence with the Princess of Orange. When, in 1688, James's queen gave birth to a son, the sisters took a lively interest in the suspicions and inquiries that arose: and Anne was easily led to believe that the child was supposititious; though later in her life she must have been convinced that he was really her brother. Before the landing of the Prince of Orange, Prince George was pledged to join him; and his wife and Lady Churchill abandoned King James on the first opportunity.

Anne.

From the Revolution till the death of William III., Anne's way of life was as quiet and obscure as it had been during the reign of her father. She did, indeed, on the prompting of her favourite, acquiesce in the act of the convention-parliament, which, postponing her place in the succession, gave the throne to William in case he should survive Mary. But the sisters soon quarrelled, and never were reconciled. The misunderstanding began in trifling questions of etiquette, quite fitted to the calibre of both of the royal minds; but considerations of real importance soon compelled the king himself to interfere. The Churchills, traitorous to their new sovereign, as they had been to the old, were known to be intriguing for the restoration of James; and they induced Anne to write secretly to her father, and declare repentance for her desertion of him. Even when William dismissed Marlborough from all his places, the princess obstinately persisted in retaining his wife in her household. After Queen Mary's death, the king and his sister-in-law went through the forms of a reconciliation: but there was no confidence on either side; and indeed the secret correspondence with Saint Germains was still carried on. The state of the succession to the crown threatened new difficulties. Anne had seventeen children, but most of them were still-born: and the Duke of Gloucester, the only one who survived infancy, died in 1700 at the age of eleven. The Jacobites, however, were unable to prevent the passing of the act of settlement, which placed the Electress of Hanover after Anne in the succession to the crown.

On the 8th of March 1702, Anne became Queen of England by the death of William, being then 38 years of age. Into her short reign there were crowded events possessing vast importance, both for the British Empire and for the whole of Europe: and her name is customarily associated with one of the most characteristic epochs in the history of English literature. Marlborough and Peterborough commanded her armies: her councils were directed in succession by Godolphin and Somers, by Harley and St John: Berkeley and Newton speculated and experimented: and the "wits of Queen Anne's time" were mustered, in poetry and in prose, under such chiefs as Prior and Pope, Swift, Addison, and Steele, Arbuthnot and Defoe. But no sovereign could have exerted less of real and personal influence than Queen Anne did, either on the national polity or on the national enlightenment. A blessed thing was it that she should have been thus powerless. For, beyond her own epicurean comforts, and the petty ceremonial of her court, there were just three ideas which her narrow and uninstructed intellect admitted: each of these ideas was full of danger to the peace and happiness of the state; and each of them was cherished by her with the hereditary stubbornness of a Stuart. She was as eager as any one of her race to enlarge the prerogatives of the crown: her father's devotion to the Church of Rome was not stronger than was her desire to increase the power of the Church of England; and she never ceased to wish earnestly that her exiled brother should be her successor on the throne. In no stage of Anne's reign was even the last of these designs impracticable: there were always able statesmen inclined to lead the way; and more than once the tide of public opinion set towards absolutism, both political and ecclesiastical. The queen, however, was not only dull and ignorant, but also indolent, fond of flattery, and accustomed from her youth to let herself be guided by stronger and more active minds than her own. Whatever her wishes might be, her actions were ruled by her female favourites. Fortunately the earlier of her two directresses, a woman of extraordinary force of

Anne. character, was both willing and able to keep in check the queen's private inclinations: not less fortunate was it that the sway exercised by the next possessor of the royal favour was speedily cut short by her mistress's death. The course of English history might have flowed less smoothly, if the Duchess of Marlborough and her husband had not become convinced that their own interest lay in supporting the principles of the Revolution; and those principles might have sustained a rude shock, if Mrs Masham and her Jacobite allies had been allowed a few months longer to mature the queen's plans and their own.

The reign of Queen Anne, lasting for twelve years, falls naturally into two unequal periods.

During the first of these, the Duke of Marlborough was paramount in the houses of parliament, and his wife in the royal closet. A ministry of Tories was formed on the queen's accession; but the leaders of it were Marlborough and Godolphin, who immediately began to edge off from their party. The principal measures were, from the beginning, in substantial conformity to the policy of King William: the war with France, hardly resisted then by any part of the nation, was prosecuted with ardour and success; and the victories of Oudenarde, Ramillies, and Blenheim, gained by the consummate generalship of Marlborough, made England formidable and illustrious throughout Europe. In the internal affairs of the kingdom, Whig principles for a time prevailed more and more; the party acquired a decided majority in the House of Commons; and the ministry came to be composed almost entirely of Whigs, some of the Tories being dismissed, and others, like the two leaders, showing the accommodating flexibility of opinion which was so rife among the statesmen of that slippery age. The Union of England and Scotland was carried through in the face of many difficulties; and, while the proceedings of the ministry in the matter were by no means perfectly pure, the measure owed its success mainly to the independent and honourable assistance of the best man among the Whigs, the accomplished and patriotic Lord Somers. During several years, in short, barriers were gradually and firmly built up against the old system, and the old parties. But other days were at hand. The domineering favourite of the queen presumed rashly on her power, and offended the self-esteem of her mistress. Mrs Masham, a poor relation of the duchess, whom she had introduced into the royal household, soothed Anne's fretful temper, gratified her vanity, and quickly, though secretly, acquired her confidence and affection; and, under the guidance of the new favourite, and her prompter Harley, the queen was encouraged to hope for the attainment of all her most cherished aims. The state of public opinion underwent a corresponding change. Even under the masterly government of William, disappointments had been felt by those who expected impossibilities from the Revolution: discontent now diffused itself very widely, the main cause being the increase of taxation which had been rendered necessary by the continental war. The Tories and Jacobites, led by some of the ablest of the statesmen, and assisted by some of the most skilful and energetic of the political writers, dexterously used the combustible materials that were accumulating, and made the Church also an active engine of mischief. The ministry saw their parliamentary majorities wasting away; they were personally treated at court with open contumely: and their ruin was completed when, still relying too boldly on their supposed strength, they impeached Sacheverell for publicly preaching in favour of Jacobitism and the divine right of kings. In August 1710 the Whig administration was ignominiously discarded.

The second period of the queen's reign began at this point. She was thenceforth governed by Mrs Masham; Mrs Masham was governed by Harley and St John, the chiefs of the new ministry; and these able and unscrupulous men exerted themselves to the utmost of their power in undoing all that had been done by their predecessors. The fruits of the war were immediately abandoned, and the allies of England shamefully betrayed, by the Treaty of Utrecht. If open attacks were not made on the constitution, it was only because the parliament could not be trusted in such a case; and because, also, the two ministerial leaders became jealous of each other, and formed separate intrigues. Harley, the Sinon of the time, corresponded both with St Germains and with Hanover; St John, more decidedly Jacobite, plotted with Mrs Masham and the queen to procure the crown for the Pretender, on the ostensible condition of his professing Protestantism. But these cabals oozed out sufficiently to alarm the honourable Tories, and to array them and the bishops against the ministry in parliament. The time, likewise, during which the danger was growing, proved too short to allow it to become ripe. Harley and Mrs Masham came to an open quarrel one evening in Anne's presence: after they had squabbled for hours, the poor queen just retained strength enough to insist that the minister should resign on the spot: she then retired, at two in the morning, and lay down on her deathbed. She was seized with apoplexy, and died on the 1st of August 1714. St John's schemes were not ready for execution; and, by the prompt activity of a few patriotic statesmen, the accession of George I. was immediately and peaceably secured. (W. S.)

Anne Boleyn ‖ St Anne's Day.

ANNE BOLEYN or BULLEN, queen of King Henry VIII., was the daughter of Sir Thomas Boleyn, a nobleman of a powerful family and numerous alliances. The daughter of the Duke of Norfolk was her mother, and during the reign of the former king her father had been honoured with several embassies. Mary, the king's sister, who married Louis XII., carried over this lady with her to France at an early age, where she imbibed the freedom, the vivacity, and the openness of manners of that nation. After the death of Louis, that queen returned to England, and Anne continued to attend her royal mistress. Having some time after left her service, she was introduced into the family of the Duchess of Alençon. On her return to England, famed for personal beauty and acquired accomplishments, the king, influenced as much by his passion for the youthful Anne as by regard to the canon law, began to express his scruples concerning his union with Catherine of Aragon. Anne was placed at court and distinguished by many marks of royal favour, and the enamoured monarch openly expressed his attachment to her; but she was possessed of too much virtue and policy to confer any improper favours. This prudent and virtuous restraint only increased the passion of the impetuous Henry; who at length came to the resolution of divorcing his queen, to make way for his favourite. Various delays and difficulties occurring to the divorce, Henry privately married Anne during the month of November 1532; and in April following he publicly declared her queen of England. The issue of this marriage was the wise and fortunate Queen Elizabeth, who was born in September following. For some time Anne enjoyed a considerable share of the royal favour, and she made use of that influence in subduing the haughty prelate Wolsey, and widening the breach between the king and the pope. But this favour was not of long continuance; for the king, ever varying in his temper, allowed jealousy to enter his bosom, which her thoughtless demeanour tended in some measure to excite. She was accused of adultery with several of the household officers, and even with her own brother Lord Rochford; and having been tried on a charge of high treason, was condemned on very inadequate evidence to be beheaded; which sentence was executed in May 1536. She resolutely denied to the last any serious guilt.

St Anne's Day, a festival of the Roman and Greek

Annealing. churches, celebrated by the Latins on the 26th of July, but by the Greeks on the 9th of December. It is kept in honour of Anne or Anna, mother of the Virgin Mary.

ANNEALING, by the workmen called *nealing*, is a process used in glass-making, and in the manufacture of certain metals. In glass-making it consists in placing the bottles, &c. whilst hot, in a kind of oven or furnace, where they are suffered to cool gradually. They would otherwise be too brittle for use. The difference between unannealed and annealed glass, with respect to brittleness, is very remarkable. When an unannealed glass vessel is broken, it often flies into a small powder, with a violence seemingly very unproportioned to the stroke it has received. In general it is in greater danger of breaking from a very slight stroke than from one of some considerable force. One of these vessels will often resist the effects of a pistol bullet dropt into it from the height of two or three feet; yet a grain of sand falling into it will make it burst into small fragments. This takes place sometimes immediately on dropping the sand into it; but often the vessel will stand for several minutes after, seemingly secure; and then, without any new injury, it will fly to pieces. If the vessel be very thin, it does not break in this manner, but seems to possess all the properties of annealed glass.

Glass.

The same phenomena are still more strikingly seen in glass drops or tears. They are globular at one end, and taper to a small tail at the other. They are the drops which fall from the melted mass of glass on the rods on which the bottles are made. They drop into the tubs of water which are used in the work; the greater part of them burst immediately in the water. When those that remain entire are examined, they discover all the properties of unannealed glass in the highest degree. They will bear a smart stroke on the thick end without breaking: but if the small tail be broken, they shiver into small powder with a loud explosion. They appear to burst with more violence, and the powder is smaller, in an exhausted receiver, than in the open air. When they are annealed they lose these properties.

Glass is one of those bodies which increase in bulk when passing from a fluid into a solid state. When it is allowed to crystallize regularly, the particles are so arranged that it has a fibrous texture. It is elastic, and susceptible of long-continued vibrations; but when a mass of melted glass is suddenly exposed to the cold, the surface crystallizes, and forms a solid shell round the interior fluid parts. This prevents them from expanding when they became solid. They therefore have not the opportunity of a regular crystallization, but are compressed together with little mutual cohesion. On the contrary, they press outward to occupy more space, but are prevented by the external crust. In consequence of the effort of expansion in the internal parts, the greater number of glass drops burst in cooling; and those which remain entire are not regularly crystallized. A smart stroke upon them communicates a vibration to the whole mass, which is nearly synchronous in every part; and therefore the effort of expansion has little more effect than if the body were at rest; but the small tail and the surface only are regularly crystallized. If the tail be broken, this communicates a vibration along the crystallized surface without reaching the internal parts. By this they are allowed some expansion; and overcoming the cohesion of the thin outer shell, they burst it, and are dispersed in powder.

In an unannealed glass vessel the same thing takes place. Sometimes the vibration may continue for a considerable time before the internal parts overcome the resistance. If the vessel be very thin, the regular crystallization extends through the whole thickness; or at least the quantity of compressed matter in the middle is so inconsiderable as to be incapable of bursting the external plate.

By the process of annealing the glass is kept for some time in a state approaching to fluidity; the heat increases the bulk of the crystallized part, and renders it so soft, that the internal parts have the opportunity of expanding and forming a regular crystallization. Annealing.

Iron.

In the manufactures in which the malleable metals are employed, annealing is used to soften a metal after it has been rendered hard by the hammer; and also to soften cast-iron, which is rendered very hard and brittle by rapid cooling.

In the manufacture of steel goods, which are first formed by the hammer, and require to be filed or otherwise treated, and in which softness and flexibility are essential to the change, annealing is absolutely necessary. This is particularly the case in making files and scissors, that the metal may be left sufficiently soft for cutting the teeth, and for filing off those parts which cannot be ground. Annealing is not less necessary in the drawing of wire, whether iron, copper, brass, silver, or gold. The operation of drawing soon gives the wire a degree of hardness and elasticity which, if not removed from time to time by annealing, would prevent the extension of the wire, and render it extremely brittle. The same operation is also necessary in rolling or flattening those metals which are in a cold state, such as brass, silver, gold, &c. The brazier who forms vessels of copper and brass by the hammer, can work upon it only for a little time before he is obliged to anneal it.

The methods often employed for annealing iron and steel are very injudicious, and materially injure the latter when it is used for making cutting instruments. After they have been formed by the hammer, they are sometimes piled up in an *open* fire, slowly raised to red heat, and then allowed as gradually to cool. By this method the surface of the steel will be found considerably scaled, from the action of the oxygen of the atmosphere. When it is remembered that steel consists of iron joined to carbon, it will be evident that the steel immediately under the scaly oxide will be deprived of its carbon, which has been carried off by the attraction of the oxygen; and, in consequence, will lose the property of acquiring that degree of hardness necessary to a cutting instrument.

Nothing, therefore, can be more obvious, than that steel particularly should be annealed in close vessels, to prevent that effect. For this purpose the goods should be placed in a trough or recess made of fire-stone or fire-brick, and stratified with ashes or clean sand, and finally covered with a thick stratum of the same; but if the size of the vessel be small, it may have a cover of its own materials. This oven or trough must now be heated by the flame of a furnace passing under and round it, till the whole is of a red heat. It must then be suffered to cool, without letting in the air. The goods so treated will be much softer than by the other method. The surface, instead of becoming scaled, will have acquired a metallic whiteness, from the presence of a small quantity of carbonaceous matter contained in the ashes in which they were imbedded. They will become so flexible also, as to allow them to bend considerably without breaking, which is very far from being the case before the operation. The fracture, before annealing, will be smooth and short; but afterwards it will be rough, exhibiting bright parts, of a crystalline appearance. Wire, especially that of iron and steel, should be treated in a similar way when it is annealed. The wire used for some purposes requires to be soft, and is sold in that state. If the wire, after finishing, when it is bright and clean, were to be annealed in contact with oxygen, it would not only lose all its lustre and smoothness, but much of its tenacity. The process above mentioned will therefore be particularly necessary in annealing finished wire, as well as in softening it from time to time during the drawing.

Copper and brass suffer much less than iron and steel from annealing in the open air, and do not require to be heated above a low red heat. If, however, the lustre is to be preserved, a close vessel would be desirable. The latter metals, after annealing, although much discoloured by the oxygen of the atmosphere, may be cleansed by immersion in a hot liquor composed of water and a small quantity of sulphuric or nitric acid. Very small brass or copper wire is frequently annealed by exposing it to the flame of hay or straw. In casting minute pieces of pig-iron, which is generally done in damp sand, the metal possesses the property of steel to such a degree as to assume, by the rapid cooling, a degree of hardness equal to hardened steel; at the same time that the articles are so brittle as to break by falling on the ground. When, however, these goods are treated in the way above directed, they acquire a degree of softness which renders them penetrable by the file, and at the same time capable of bending. In this state they are much less tenacious than steel, but still so much so as to have been sold in the form of cutlery for steel.

The change which metals undergo by annealing is not yet thoroughly understood. Most of the malleable metals are susceptible of two distinct forms, one called the crystalline form, which they assume by slow cooling; and the other the fibrous, which is acquired by hammering or rolling. When this, however, is carried beyond a certain point, the metal becomes so hard that it is not capable of being bent far without breaking. All the malleable metals in the ingot or in their cast state are brittle, and exhibit a crystalline fracture. By hammering or rolling they become more tenacious, and break with difficulty, exhibiting what is called a fibrous fracture. At the same time they become stiffer and more elastic. They lose the latter properties by annealing, but become more malleable. If the annealing, however, be long continued, the malleability diminishes, and they again have a crystalline fracture. Zinc by wire-drawing becomes very flexible, and possesses a degree of tenacity not inferior to that of copper; but, if it be kept in boiling water for a length of time, it will resume its original brittleness, and show a crystalline appearance when broken. This proves that the particles of metals can change their arrangement without losing their solid form; which is still more strongly confirmed by the fact, that brass wire loses its tenacity by exposure to the fumes of acids, and even by the presence of a damp atmosphere. This is not caused by the moisture, but by the action of air upon the moistened surface. The manufacturers of common pins are obliged to keep their wire in a dry atmosphere, or immersed in water. If the wire be first moistened, and then exposed to the air, it will assume the brittle state much sooner. In this condition it breaks with a crystalline fracture, similar to that exhibited by an ingot. When a steel plate, such as a watch-spring, has been once tempered, the operation of simply rubbing it bright will render it soft and elastic. The same change is brought about by slightly hammering it. It, however, resumes its elastic state by being carefully heated till it becomes of a blue colour. If the heat be continued to redness, particularly in a close vessel, it becomes perfectly annealed. (C. S—R.)

ANNECY, a city in the kingdom of Sardinia, the capital of the province of Genevois, in the duchy of Savoy. It is at the foot of the mountain Semina, on the banks of the lake of that name. It is the most industrious place in Savoy, having manufactures of cotton goods, of hats, glass, and earthenware, besides several distilleries and tanneries; and near it are some iron-works. It contains a cathedral, a church, five monasteries, and the same number of nunneries. The relics of St Francis de Sales, preserved in St Mary's Church, draw many prilgrims annually to the city. Pop. 9000. Long. 6. 9. E. Lat. 45. 53. N. The lake of Annecy is about nine miles in length by two in breadth, and its surface is 1400 feet above the sea. It lies 20 miles south of Geneva, in the midst of exquisite mountain scenery.

ANNELIDES, or ANNELIDA, worms with red blood, are the first class of the third grand division of animals, the *Articulata*. See HELMINTHOLOGY.

ANNESLEY, ARTHUR, Earl of Anglesea, and lord privy seal in the reign of King Charles II., was the son of Sir Francis Annesley, baronet, Lord Mount-Norris, and Viscount Valentia, in Ireland, and was born at Dublin on the 10th of July 1614. He was for some time at the university of Oxford, and afterwards studied the law at Lincoln's Inn. He had a considerable share in public transactions, for in the beginning of the civil war he sat in the parliament held at Oxford; but afterwards became reconciled to the opposite party, and was sent commissioner to Ulster, to oppose the designs of the rebel Owen Roe O'Neal. He engaged in several other affairs with great success. He was president of the council of state after the death of Cromwell, and was principally concerned in bringing about the Restoration; soon after which King Charles II. raised him to the dignity of a baron, by the title of Lord Annesley of Newport-Pagnel, Bucks; and a short time after he was made Earl of Anglesea. During that reign he was employed in some important affairs, was made treasurer of the navy, and for some time held the office of lord privy seal. He was a person of great abilities, of very extensive learning, and was well acquainted with the constitution and laws of England. He died in April 1686, in the 73d year of his age. In his lifetime he published the following pieces:—

1. Truth unveiled, in behalf of the Church of England; being a Vindication of Mr John Standish's Sermon, preached before the King, and published by his Majesty's command. 1676, 4to. To which is added, A short Treatise on the subject of Transubstantiation. 2. A Letter from a Person of Honour in the Country, written to the Earl of Castlehaven; being observations and reflections on his Lordship's Memoirs concerning the Wars of Ireland. 1681, 8vo. 3. A true Account of the whole Proceedings between James Duke of Ormond and Arthur Earl of Anglesea, before the King and his Council, &c. 1682, folio. 4. A Letter of Remarks upon Jovian. 1683, 4to. Besides these, he wrote several other works, some of which were published after his decease; as, 5. The Privileges of the House of Lords and Commons, argued and stated in two conferences between both Houses, April 19 and 22, 1671: To which is added, A Discourse, wherein the rights of the House of Lords are truly asserted; with remarks on the seeming arguments and pretended precedents offered at that time against their Lordships. 6. The King's Right of Indulgence in Spiritual Matters, with the Equity thereof asserted. 1688, 4to. 7. Memoirs, intermixt with moral, political, and historical observations, by way of discourse, in a Letter to Sir Peter Pett. 1693, 8vo.

ANNEXATION, the act of annexing or uniting one thing to another. In law it is applied to the uniting of lands or rents to the Crown. In *Scottish Law* it also signifies the appropriation of church-lands to the Crown, and of lands lying at a distance from the kirk to which they belong to another kirk to which they are more contiguous.

ANNIVERSARY, the annual return of any remarkable day. Anniversary days, in old times, more particularly denoted those days in which an office was yearly performed for the souls of the deceased, or on which the martyrdom of the saints was yearly celebrated in the church.

ANNOBOM, or ANNABONA, a small island of Africa, on the west coast of Loango. It lies in Long. 5. 35. 7. E. and Lat. 1. 24. 3 .S., 190 miles west of Cape Lopez, is about four miles in length, and two in breadth, and rises abruptly from an unfathomable depth to the height of 3000 feet above the level of the sea. It is a beautiful island, exhibiting a succession of little valleys, with fine outlines of steep mountains richly clothed with wood, while every ledge and crevice

gives nourishment to a rich luxuriance of vegetation, and the precipitous surfaces are tinged with every variety of colour. Vessels touch at Annobom for refreshments, of which the supply is abundant, including swine, sheep, goats, fowls, bananas, plantains, cassada, sweet potatoes, pines, and tamarinds. Guinea-fowl, large and finely flavoured, are particularly plentiful. Cassada, cotton, and sugar-cane are cultivated with care and success. The population amounts to about 3000, mostly collected in a large village near the north-east point of the island, off which is the only tolerably safe roadstead for shipping. The people are negroes, perfectly harmless, and with some vague idolatrous belief in the Roman Catholic religion. In their dealings with strangers they are not strictly honest, but as much so as can reasonably be expected. Their houses are small and rudely constructed. Supplies are procured from them more readily by barter than for money. Cheap tawdry kerchiefs, old clothes, muskets, fish-hooks, cutlery, trinkets, rum, and tobacco, are the objects chiefly coveted. Their government was a sort of oligarchy vested in five persons, who assumed office by turns, strangely enough measuring its tenure by the arrival of ships, each magistracy lasting during the period of the arrival of ten. The island received its name from its having been discovered by the Portuguese on New-year's day, A.D. 1473. In 1778 it came into the possession of Spain; and in 1827 it was taken possession of by the English, but was restored to Spain in 1843.

ANNONÆ PRÆFECTUS, an extraordinary magistrate at *Rome*, whose business it was to prevent a scarcity of provisions. and to regulate the price, weight, and fineness of bread.

ANNONAY, a town of France, in the department of Ardeche, situated at the confluence of the rivers Cance and Deaume, 37 miles south of Lyons. It is a very prosperous manufacturing town, irregularly built, and presents little worthy of notice, except an obelisk in honour of the celebrated Montgolfier (who was a native of this place), and a suspension bridge in its vicinity, the first constructed in France. The principal manufacture is that of paper, long reckoned the best in France. It has also manufactures of gloves, cotton, woollen, and silk. Pop. 9893.

ANNUALRENT, in *Scottish Law*, denotes the yearly interest or profit due by a debtor in a sum of money to a creditor for the use of it.—A *Right of* ANNUALRENT was the original method in Scotland of burdening lands with a yearly payment for the loan of money, before the taking of interest was allowed.

ANNUITIES.[1]

THE doctrine of Compound Interest and Annuities-certain is too simple ever to have occupied much of the attention of mathematicians: inquiries into the values of interests dependent upon the continuance or the failure of human life, being more interesting and difficult, have occupied them more, but yet not so much as their importance would seem to demand; the discoveries both in Pure Mathematics and Physics, especially those of Newton, which distinguished the close of the seventeenth century, having provided them with ample employment of a more interesting kind, ever since the subjects of this article were submitted to calculation.

Fermat, Pascal, and Huygens, by laying the foundation of the doctrine of probabilities, about the middle of that century, first opened the way to the solution of problems of this kind. The earliest mathematical publication on probabilities, the little tract of Huygens, *De Ratiociniis in Ludo Aleæ*, appeared in 1658; and in 1671 his celebrated countryman John de Witt published a treatise on Life-Annuities in Dutch. (Montucla, *Hist. des Math.* tome iii. p. 407.) This, however, appears to have been very little known or read, and to have had no sensible influence on the subsequent progress of the science, the origin of which may be properly dated from the publication of Dr Halley's paper on the subject, in the *Philosophical Transactions* for the year 1693 (No. 196). That celebrated mathematician there first gave a table of mortality, which he had constructed from observations made at Breslaw, and showed how the probabilities of life and death, and the values of annuities and assurances on lives, might be determined by such tables; which, he informs us, had till then been only done by an imaginary valuation. Besides his algebraical reasonings, he illustrated the subject by the properties of parallelograms and parallelopipedons: there are, perhaps, no other mathematical inquiries, in the prosecution of which algebra is entitled to so decided a preference to the elementary geometry as in these, and this example of the application of geometry has not been followed by any of the succeeding writers.

In the year 1724 M. de Moivre published the first edition of his tract entitled *Annuities on Lives*. In order to shorten the calculation of the values of such annuities, he assumed the annual decrements of life to be equal; that is, that out of a given number of persons living at any age, an equal number die every year until they are all extinct; and upon that hypothesis he gave a general theorem, by which the values of annuities on single lives might be easily determined. This approximation, when the utmost limit of life was supposed to be 86 years, agreed very well with the true values between 30 and 70 years of age, as deduced from Dr Halley's table; and the method was of great use at the time, as no tables of the true values of

[1] Hardly any terms are made use of in this article which may properly be considered technical. But since it is desirable that the reader should have perfectly clear and well-defined ideas of the terms that are employed, in the demonstrative part, which follows the historical, a few have been defined in the paragraphs where they are first introduced; and we here give those terms in alphabetical order, with the numbers of the paragraphs in which their definitions are given:—

Term.	*Paragraph.*
Annuity	3
Annuity, Certain	4
Annuity, Deferred	20
Annuity, Life	31
Annuity, Temporary Life	58
Annuity on any Life or Lives	62
Assurance on any Life or Lives	77
Mortality, Table of	32
Years' Purchase, No. of, that an Annuity is worth	6

History. annuities had then been calculated, except a very contracted one inserted by Dr Halley in the paper mentioned above. But, upon the whole, this hypothesis of De Moivre has probably contributed to retard the progress of the science, by turning the attention of mathematicians from the investigation of the true law of mortality, and the best methods of constructing tables of the real values of annuities.

The same distinguished analyst also endeavoured to approximate the values of joint lives; but it has since been found that the formulæ he gave for that purpose are too incorrect for use. Mr Thomas Simpson published his *Doctrine of Annuities and Reversions* in the year 1742, in which the subject is treated in a manner much more general and perspicuous than it had been previously. His formulæ are adapted to any table of mortality; and, in the seventh corollary to his first problem, he gave the theorem demonstrated in the 149th number of this article, to which we owe all the best tables of the values of life-annuities that have since been published.

In the same work he also gave a table of mortality deduced from the London observations, and four others calculated from it, of the values of annuities on lives, each at three rates of interest; the first for single lives, the three others for two and three equal joint lives, and for the longest of two or of three lives.

These were the first tables of the values of joint lives that had been calculated; for although Dr Halley had shown, half a century before, how such tables might be computed, and had taken considerable pains to facilitate the work, the necessary calculations by the methods known previous to the publication of Mr Simpson's treatise were so very laborious that no one had had the courage to undertake them. And unfortunately the mortality according to the London table was so much above the common average, that the values of annuities in Mr Simpson's tables were much too small for general use.

In the year 1746 M. Deparcieux published his *Essai sur les Probabilités de la Durée de la Vie Humaine*, in which he gave several valuable tables of mortality deduced from the mortuary registers of different religious houses, and from the lists of the nominees in the French tontines; also a table of the values of annuities on single lives, at three rates of interest, calculated from his table of mortality for the tontine annuitants. These tables were a great acquisition to the science, as, before their publication, there were only two extant that gave tolerably exact representations of the true law of mortality—Dr Halley's for Breslaw, and one constructed but a short time before by M. Kersseboom, principally from registers of Dutch annuitants. Those of M. Deparcieux for the monks and nuns were the first ever constructed for the two sexes separately; and by them the greater longevity of females was made evident.

The work commences with an algebraical theory of annuities-certain; but the principal essay, *On the Probabilities of the Duration of Human Life*, is perfectly intelligible to those who have not studied mathematics. It is written with great judgment and perspicuity, but contains very little more than the explanation of the construction of his tables, some of which relate to tontines; and he did not avail himself to the extent he might have done, of the excellent tract of Thomas Simpson.

This work, however, appears to have been more read upon the Continent, and to have contributed more to the diffusion of this kind of information there, than all the other writings on the subject. The article *Rentes Viagères* in the French *Encyclopédie* is acknowledged to have been taken entirely from it, as was also the article Vie, *durée de la;* and these are proofs, among many others that might be produced, how little M. d'Alembert and the principal mathematicians his contemporaries attended to the subject.

In the year 1752 Mr Simpson published, in his *Select Exercises*, a supplement to his doctrine of Annuities; wherein he gave new tables of the values of annuities on two joint lives, and on the survivor of two lives, much more copious than those he had inserted in the principal work; but these also were calculated from his London table of mortality.

The celebrated Euler, in a paper inserted in the *Memoirs of the Royal Academy of Sciences at Berlin* for the year 1760, gave a formula by which the value of an annuity on a single life of any age may be derived from that of an annuity on a life one year older; which formula was included in that given by Mr Simpson 18 years before for effecting the same purpose in the case of any number of joint lives; and by this compendious method M. Euler calculated a table of the values of single lives from M. Kersseboom's table of mortality.

The first edition of Dr Price's *Observations on Reversionary Payments* was published in 1770, and its chief object was, to give information to persons desirous of forming themselves into societies for the purpose of making provision for themselves in old age, or for their widows. When tables of the values of single lives, and of two joint lives, are given, the methods of determining the terms on which such provisions can be made with safety to all the parties concerned are very simple, and were at that time well understood in theory by the mathematicians who had studied the subject; but, for want of the requisite tables, the algebraical formulæ had till then been of little practical utility.

In the prosecution of this laudable design, Dr Price was obliged to have recourse to approximations. He informs us, that by following M. de Moivre too implicitly in his rules for determining the value of two joint lives, he was led into difficulties which convinced him that they were not only useless but dangerous: he therefore calculated a table of these values upon M. de Moivre's hypothesis of the decrements of life being equal, and its utmost limit 86 years, from a correct formula given by Mr Simpson in his doctrine of Annuities (Cor. 5, Prob. 1). By this, and a table of the values of single lives, calculated by Mr Dodson on M. de Moivre's hypothesis, he was enabled to give answers tolerably near the truth, to some of the most interesting questions of this kind, and to show that the plans of several of the societies then recently established, were quite inadequate; and instead of the benefits they promised, could only, in the end, produce disappointment and distress, unless they either dissolved or reformed themselves.

The work also contained instructive dissertations on the probabilities and expectations of life, and on the mean duration of marriage and of widowhood; besides accounts of some of the principal societies which had then been formed for the benefit of old age and of widows, with observations on the method of forming tables of mortality for towns, and two new tables of that kind constructed from registers kept at Norwich and Northampton. Mr Morgan's *Doctrine of Annuities and Assurances* was published in 1779, containing tables of the values of single lives, of two equal joint lives, and of two lives differing in age by 60 years, calculated from the Northampton table of mortality. And in the same year M. de Saint-Cyran published his *Calcul des Rentes Viagères sur Une et sur Plusieurs Têtes*, wherein the valuation of annuities on lives is treated algebraically, but in a manner much inferior in all respects to that of Mr Simpson; and six tables are given of the values of annuities—on single lives, on the survivor of two lives, and on the last survivor of three, calculated

from M. Kersseboom's table of mortality. Although the values in the cases of two and of three lives were only determined by approximation, these tables were, just then, a valuable acquisition to the science; but their use was entirely superseded only four years after, by the publication of others much more valuable.

The fourth edition of Dr Price's *Observations on Reversionary Payments* appeared in 1783. One of the best effects of the preceding editions on the progress of the science had been, to direct the public attention to these inquiries, by showing their important uses in the affairs of life; and to procure the requisite *data* for forming tables of mortality, that should illustrate the laws according to which human life wastes under different circumstances, by exciting the curiosity of intelligent men who had the necessary leisure and means of information. The ingenious author had accordingly been furnished with the necessary abstracts of mortuary registers which had been kept with these views, by Dr Haygarth at Chester, Dr Aikin at Warrington, and the Rev. Mr Gorsuch at Holy-Cross, near Shrewsbury, since the publication of the first edition; also by Mr Wargentin, with the mean numbers both of the living and the annual deaths in all Sweden and Finland for 21 successive years; in all of which the sexes were distinguished; and from these *data* he constructed tables of mortality that threw great light on the subject. He also inserted in this edition an improved table of mortality for Northampton; and, what had been so long wanted, a complete set of tables of the values of annuities on single lives at six rates of interest, and on two joint lives at four, all calculated from the new Northampton table. The combinations of joint lives were sufficiently numerous to admit of all the values not included being easily interpolated. Besides these, he also gave tables of the values of annuities on single lives from the Swedish observations, both with and without distinction of the sexes, and on two joint lives without that distinction.

The values given in these tables are too low for the general average of lives at all ages under 60; but in the treatise of Mr Baron Maseres on the *Principles of the Doctrine of Life Annuities*, which was published in the same year (1783), others were given, calculated from the table of mortality which M. Deparcieux constructed from the lists of the nominees in the French tontines. The tables for single lives are calculated at twelve different rates of interest from 2 to 10 *per cent.*, but those for joint lives only at $3\frac{1}{2}$ and $4\frac{1}{2}$ *per cent.*; and the combinations they include are only those of ages that are equal, or that differ by 5 or 10 years, and the multiples of 10.

There is reason to believe that the values in these tables, at all ages under 75 or 80 years, are nearer the truth, for the average of this country, than any others then extant; but certainly for the average of lives on which annuities and reversions depend. After that period of life, however, they are too small; and, in most cases, it is difficult to derive the values of joint lives from them with sufficient accuracy, on account of the contracted scale they have been calculated upon.

It was not Dr Price's object to deliver the elements of the science systematically; but he treated most parts of it with great judgment, enriched it with a vast collection of valuable facts and observations, and corrected several errors into which some of the most eminent writers upon it had fallen. The mathematical demonstrations (which are given in the notes) are much inferior to the rest of the work.

The values of reversionary sums and annuities, which depend upon some of the lives involved failing according to assigned orders of precedency, had been approximated by Mr Simpson in his *Select Exercises*, and by Mr Morgan in his *Doctrine of Annuities*; but the latter gentleman first gave accurate solutions of problems of this kind, in the *Philosophical Transactions* for the years 1788, 1789, 1791, 1794, and 1799.

Mr Baily's *Doctrine of Life Annuities and Assurances* was published in 1810. In it the whole subject is treated, except the construction of tables of mortality, on which the practical application of all the rest depends. In consequence of the author having adopted Mr Simpson's notation, this work presented a more perspicuous exposition of the whole theory, especially of the improvements made in it between the time when Mr Simpson wrote and the date of its publication, than had previously appeared. And in an appendix to it, published in 1813, principally for the purpose of explaining the construction and uses of tables for determining the values of life-annuities, calculated at a vast sacrifice of time and labour by Mr George Barrett, since deceased, formulæ were given for calculating from tables of that kind the values of temporary and deferred life-annuities and assurances, and also for determining the values of annuities and assurances when the annuity or the sum assured, instead of remaining always the same, increases or decreases from year to year by equal differences, with considerably greater facility and expedition than the same things could have been effected with by the tables and methods of calculation in previous use.

Except by these improvements, and the solution of the problems above stated to have been first given by Mr Morgan, which were severely criticised and given anew, with some amendments besides the important one of the notation in Mr Baily's work, the science had not been materially advanced, during a period of more than 30 years, which had elapsed since the appearance of the fourth edition of Dr Price's observations, when Mr Milne published his *Treatise on the Valuation of Annuities and Assurances on Lives and Survivorships*, in the year 1815.

The work consists of two volumes; the first is mathematical, the second entirely popular, except the notes and a few of the tables. The algebraical part of this article is merely a short abstract of the first volume, and may serve as a specimen of the manner in which the subject has been treated there; but the construction of tables of mortality, which forms the subject of the third chapter, has not been noticed here; neither is the valuation of reversionary sums or annuities depending upon assigned orders of survivorship treated in the present article; and these are parts of the work which will not be found the least interesting to mathematicians.

The second volume contains upwards of 50 new tables, with a few others that had been published before, but have been reprinted either on account of their value or scarcity, or both. Four of the new ones are tables of mortality constructed by the author, from registers kept at Carlisle and Montpellier, and in all Sweden and Finland, since the period of the observations Dr Price made use of: the sexes are distinguished in the tables for Sweden and Montpellier, but not in that for Carlisle. This last is the only table, besides those for Sweden and Finland, applicable to the mass of the people, that has been formed from the necessary *data*,—enumerations of the living, as well as registers of the deaths, in every interval of age.

Twenty-one of these tables, being the seventeenth to the thirty-seventh inclusive, in the collection at the end of the work, render it easy to apply the algebraical formulæ to practical purposes, and numerous examples of such applications are given. They have all been calculated from the Carlisle table of mortality; those of the values of life-annuities on the same extensive scale with those

which Dr Price derived from the Northampton table. It is the author's opinion that the values of interests dependent upon the continuance or the failure of life may be derived from them more correctly than from any others then extant, and he has taken considerable pains to assist his readers in judging of this for themselves.

Besides the tables, the principal contents of the second volume are explanations of their construction and uses. Many of them relate to the progress of population,—the comparative mortality of different diseases, of different seasons,—and of the two sexes at every age, the proportion of the sexes at birth, and that of the born alive to the still-born of each sex.

It will be found that the author has collected records of facts and observations of great value, and that he has endeavoured to present the information they afford in the forms best calculated for the further prosecution of these inquiries.

Mr Gompertz's *Sketch of an Analysis and Notation applicable to the estimation of the value of Life Contingencies* was read at a meeting of the Royal Society on the 29th of June 1820, and printed in the Society's Transactions for that year.

The second edition of Mr Morgan's *Principles and Doctrine of Assurances and Annuities on Lives* was published in 1821. The formulæ for determining the values of contingent reversions, first given by the author in the *Philosophical Transactions*, as above stated, were in this second edition substituted for the approximations given in the first; and it contains tables of the values of annuities on single and joint lives, calculated from the Northampton and Sweden tables of mortality, and taken from Dr Price's *Observations on Reversionary Payments*.

This edition contains nothing new, except a table on the two last pages, showing the number of persons whose lives were insured in the Equitable Society, who died of each disease in each decade of age from 10 years to 80, and above 80 years of age, during a term of 20 years commencing with 1801. Also (in the last line of the table) " the number assured during the same term" in each of these intervals of age. The obvious meaning of this expression would seem to be, *the number of persons on whose lives assurances were effected by the Society during these* 20 *years, in each interval of age*. This is the sense in which Mr Babbage understood it, and therefore drew wrong inferences from it (in his *Comparative View of Life Insurance Institutions*, p. 63 and table 13). The late Dr Young was also misled by it, and appears to have taken those for the mean numbers of the lives on which the society had policies in force in the several intervals of age during these 20 years; and thence concluded that during these 20 years, according to that table, the mean number of lives of all ages on which the society had policies in force was more than 150,000, and that only one out of 1500 of them died annually. (*Philosophical Transactions*, 1826, p. 287.)

Indeed Mr Morgan himself, on the page preceding his table, stated that it contained an account of all the deaths which had happened in the society during 20 years, " among a population exceeding 150,000 persons."

If the numbers only in that last line of the table had been given, without any explanation of them, it would, upon due consideration, have been conjectured that they could be no others than the sums of the numbers of lives insured by the society which were found to be in those intervals of age at one and the same period in each of those 20 years; that is, 20 times the mean numbers of them in the several intervals during the same term. But neither of Mr Morgan's explanations of them would admit of that construction.[1]

The present article was first published in the Supplement to this Encyclopædia in 1816.

In the article on the Law of Mortality in that Supplement, which appeared in 1822, it was shown that, according to Mr Morgan's statement, made at a general court of the Equitable Society in the year 1800, of the mortality which had taken place among the lives insured by that society as compared with the Northampton table, the mortality among those lives in each decade of age from 10 years to 50 was very nearly the same as in the Carlisle table of mortality; also that, above 50 years of age, the difference, upon the average, was not great. And early in 1826 were published *Tables of Life Contingencies*, by Mr Davies, and *A Comparative View of the various Institutions for the Assurance of Lives*, by Mr Babbage; in each of which works was given a table of the mortality which had prevailed among the lives insured in the Equitable Society at all ages above 10 years, constructed from that statement of Mr Morgan.

Mr Babbage gave also a table of the values of annuities on single lives of all ages above ten years, derived from his table of mortality above mentioned; and the indefatigable Mr Davies gave tables of the values of annuities on single and joint lives, calculated both from his table of mortality above mentioned and from the Northampton table, rather fuller and more complete than any that had previously been published, except that those derived from the law of mortality in the Equitable Society necessarily included no ages under 10 years. The values according to the Northampton table were given only at the rates of 3 and 4 per cent. interest; but Mr Davies, not content to take them on Dr Price's authority, has, like Mr Barrett, calculated them anew, and, as well as the other values of annuities, has carried them to four places of decimals. This author's comprehensive little book also contains many other tables of the values of annuities and assurances on lives and survivorships, with one of the values of policies of assurance, calculated from the Northampton table of mortality at 3 per cent. interest, which, as well as many another single table contained in it, must have cost him much time and labour; and those derived from the Northampton table of mortality must be very valuable to such of the assurance companies as take that table for their guide in transacting business.

Mr Babbage and Mr Davies also gave formulæ and tables similar to, or not materially different from, those of Mr Barrett above mentioned, for determining the values of temporary and deferred, as well as increasing or decreasing annuities and assurances on single lives; the tables of Mr Babbage being derived from his table of mortality in the Equitable Society, and from the Carlisle table; that of Mr Davies from the Northampton table of mortality alone.

Mr Morgan, in the statement on which those tables of Mr Babbage and Mr Davies were founded, contented himself with the use of two simple digits only, to express the proportion of the mortality in the Equitable Society to that in the Northampton table in each decade of age; and although that gentleman for twenty-five years after 1800, when that statement of the thirty years' previous observations was made, continued, in Notes on Dr Price's *Observations on Reversionary Payments*, and in his addresses to the general courts of the Equitable Society, to state that the proportions still remained the same, the

[1] See the note at the end of this Historical Introduction.

observations extending over a period of fifty-five years, he never gave any statement more full or distinct.

These were but scanty materials certainly to construct a table of mortality from; and yet the agreement between the tables formed from them, and the best of other existing tables of mortality, is very remarkable.

A committee of the House of Commons on friendly societies having been appointed in 1827, chiefly for the purpose of inquiring into the law of mortality, and the values of life-annuities and assurances in this country, the report of that committee, by bringing the subject prominently before the public, and exciting attention to well-established but much neglected results of inquiries into it, had the effect of correcting to a considerable extent opinions upon it, taken upon trust without due examination, and generally diffused. The establishment of many new assurance companies, and the increasing prevalence of life-assurance for 15 or 20 years before, by exciting discussion and examination of their rates, had also contributed to produce that effect. At length the members of the Equitable Assurance Society, as the period of the decennial investigation of their affairs in 1829 approached, expressed a desire to avail themselves of the information respecting the law of mortality in the society which the office books might afford, for estimating and dividing their profits; and in 1828 Mr Morgan published a pamphlet entitled *A View of the Rise and Progress of the Equitable Society*, in which (p. 42) he gave the following " table of the decrements of life in the society during the preceding 12 years."

TABLE (a).

1	2	3	4
Age.	Number.	Died.	Should have died.
20 to 30	4,720	29	68
30 to 40	15,951	106	243
40 to 50	27,072	201	506
50 to 60	23,307	339	545
60 to 70	14,705	426	502
70 to 80	5,056	289	290
80 to 95	701	99	94

In the same place, the author informs his readers that " in his former statement (without mentioning which of them) he was not aware of the great number of instances in which there were several policies on one and the same life." Also that " the present is, in fact, the only correct table of the decrements of life in the society."

In the same pamphlet the author has given a table to show the law of mortality among the lives insured in the Equitable Society, founded upon his last statement; also a table of the expectations of life, and one of the values of annuities on single lives at three *per cent. per annum* interest, both derived from that table of mortality, none of them including any age under 20 years.

The author of the present article, when preparing this historical sketch, not clearly understanding the import of the numbers in the second column of this table (a), nor the last line in the table of deaths by the different diseases, given at the end of Mr Morgan's work on annuities (2d edit. 1821)—having also some doubts about the statement made in 1800—wrote to Mr Morgan, and requested the desired information respecting them, when that gentleman forwarded him the following:

1. That the second column should have been headed, " Number of persons living at the beginning of each year during the last 12 years;" and the fourth, " the number which should have died, according to the Northampton table."
2. That as to the table at the end of his treatise on annuities, he knew the numbers of deaths by the different diseases to be correct; but " the numbers in the last line of that table were those of the *policies*, which he had since found greatly to exceed the numbers of the *members*."
3. Upon his statement of 1800 Mr Morgan made no observation.

From the first part of the information thus obtained, it appears that the number in the second column on any line in table (a), is twelve times the mean number of lives in the interval of age set against it, on which the Equitable Society had policies in force during these 12 years; so that, in a society similar in all other respects, in which the law of mortality was constantly the same, and the number of lives in each interval of age was always just 12 times as great as in the Equitable during these 12 years, the population and mortality would be as in columns 2 and 3 of the following table (b).

TABLE (b).

1	2	3	4	5	6
			Of whom would die annually according to		
			Our calculations from		Mr Morgan's calculations from
Between the Ages of	Number constantly living.	Of whom die annually.	Mr Morgan's Table of Mortality in Equitable Society.	The Northampton Table of Mortality.	
20 & 30	4,720	29	37	74	68
30 & 40	15,951	106	150	299	243
40 & 50	27,072	201	337	648	506
50 & 60	23,307	339	536	780	545
60 & 70	14,705	426	664	726	502
70 & 80	5,056	289	460	461	290
80 & 95	701	99	146	147	94
Totals	91,512	1489	2330	3135	2248

If our inferences in the 4th and 5th columns of this table from Mr Morgan's *data* in the 2d and 3d be correct,[1] neither Mr Morgan's in the 6th column, nor his table of mortality, nor consequently those of the expectations and values of lives above mentioned, can have been accurately derived from the same *data*.

But even with these *data* we have reason to believe that Mr Morgan is not well satisfied, and that that gentleman has since been able to form a table from much more unexceptionable documents, which shows the probabilities

[1] It may be proper to show here, how our numbers in columns 4 and 5 have been determined. For this purpose we give as an example the manner in which the 2d in col. 5 has been calculated.

Expectation of life at $\left\{\begin{matrix} 30 = 28{\cdot}27 \times 4385 \\ 40 = 23{\cdot}08 \times 3635 \end{matrix}\right\}$ number annually attaining that age $= \left\{\begin{matrix} 123{,}964 \\ 83{,}896 \end{matrix}\right\}$ number living above $\left\{\begin{matrix} 30 \\ 40 \end{matrix}\right.$

The differences are the numbers between 30 and 40; 750 dying annually, and 40,068 constantly living.

And 40,068 : 750 : : 15,951 : 299 See article on LAW OF MORTALITY.

History.

of life, especially in the latter periods, to be much nearer the probabilities of life among mankind in general than he had previously imagined.

It is satisfactory to find Mr Morgan at last coming into an opinion, of the truth of which, evidence had previously been adduced sufficient to convince almost all who attended to it; and, trusting that he will publish the results of his latest inquiries on the subject, we shall take no further notice here of the table of the values of annuities in his pamphlet above mentioned, which, otherwise, we could not with propriety have avoided.

Mr Morgan (*Pamph.* p. 42 and 43) asserts that a comparison of columns 3 and 6 of this table (b) affords a striking proof of the accuracy of the Northampton table; but, to judge of that, we consider it is not column 6, but 5, which should be compared with column 3.

In the *Transactions of the Cambridge Philosophical Society*, vol. iii. part 1, are two papers by Mr Lubbock; the first *On the Calculation of Annuities, and on some Questions in the Theory of Chances* (read May 26, 1828); the other *On the Comparison of various Tables of Annuities* (read March 30, 1829).

In the year 1808 government commenced granting life-annuities at prices calculated from the Northampton table of mortality, and continued so to grant them for 20 years, at a great loss to the nation, especially when the lives were young, as was well known at the time to those who understood the subject; and was mentioned more than once by the author of the present article, to a very able and well-informed member of the government, not long after they commenced granting them. But none were then granted on lives under 35 years of age; and the gentleman alluded to only observed, that the applicants for annuities were principally aged persons, and it was desirable that a safe and advantageous mode of employing their savings should be afforded them. After the year 1816 those annuities were granted to persons of all ages above 21 years.

Although the *data* necessary for determining the law of mortality among the people, and the values of pecuniary interests dependent upon the continuance or the failure of human life, cannot be obtained without the active concurrence of many persons of influence and authority; yet, for all the tables containing information of that kind relative to this country, and published before the year 1829, the public were indebted to the zeal and industry, and the separate efforts, of a few individuals.

But in March 1819 Mr Finlaison was appointed by government, with all the aids they could afford him, including proper assistants, and access to the registers of the nominees in tontines, and others on whose lives annuities had been granted by government for more than a hundred years before; in which registers the exact ages at which the annuitants were nominated, and those at which they died, were stated.

Thus the *data* not otherwise accessible being provided, and the labour lessened by the number of calculators employed—the expense also being defrayed by the public—at the end of ten years, viz. in March 1829, Mr Finlaison made a report to the Lords of the Treasury, which was printed by order of the House of Commons, and, in tables filling 50 folio pages, shows the rates of mortality, and the values of annuities on single lives at all ages, among many different classes of annuitants, both separate and combined; the sexes being generally distinguished both in exhibiting the law of mortality and the values of annuities.

These, from the number and accuracy of the *data*, are more valuable than any thing of the same kind that had previously been published; but it is the values of annuities only which we have to notice here.

The lives on which annuities depend will generally be somewhat better (by which we here mean, will attain to greater longevity) than the general average of the population, though probably not nearly so much better as many believe them to be. The prevailing error in the popular estimate on this subject appears to have arisen in great measure from comparing the mortality among annuitants and assured lives, with that represented to take place by tables of mortality erroneously considered to correspond with the general average of the people; while, from being constructed on erroneous principles, and from insufficient *data*, or else being derived from observations made where the mortality was and is much greater than in Britain, the mortality according to these tables was considerably greater than that which actually prevails among the bulk of the people here. Proofs of this will be found under the article LAW OF MORTALITY.

That the lives on which annuities and assurances depend cannot be so very select or so much better than the common average as has generally been supposed, might reasonably be expected on these grounds:—

1. As to annuitants.

The lives are not all chosen on account of their presumed goodness; for many persons who have no occasion to provide for others who may survive them, purchase annuities on their own lives, only that they may themselves enjoy the whole benefit of the purchase-money, both principal and interest, during their lives.

And the greatest recommendation of these lives seems to be, that they are generally prudent persons, of temperate and regular habits.

Many other persons, especially females, spendthrifts, and faithful servants, enjoy annuities bequeathed to them by their deceased relatives, masters, or mistresses, as the most eligible provision for their future comfort and security from want; and there seems little ground to suppose them to be better lives than the common average of the same age and sex.

2. In such cases as tontines, where most of the lives are selected for their presumed goodness, the best criterion probably is, hereditary longevity in the family of the nominee; but partiality for their own friends or kindred often has considerable influence in biassing the judgment of those who select them.

That they will generally be persons of good constitutions and regular habits when selected, is all that is likely to be obtained under these circumstances; and that is also the case with the average of the population in comfortable circumstances.

Whatever the constitutions and habits of annuitants may be, the annuities held by them during their own lives, by protecting them from many of the wants, cares, and anxieties which the bulk of the people are exposed to, no doubt contribute to their longevity. But where powerful motives to raise money by the sale of an annuity on a person's own life exist, it is extremely difficult to prevent him from parting with it, whatever precautions may have been taken with that view; and with it, he also loses that help to longevity.

3. Insured lives are also generally supposed to be much better than the average of the population, as it is incumbent upon the insurance offices to be cautious in selecting them.

But bad lives, by the failure of which persons interested in them would sustain loss, are most likely to be offered, and are continually offered, for insurance; and there is reason to believe that all the caution in selection which the offices in general can exercise, is necessary to keep the lives insured up to the average goodness of the bulk of the population;—supposing always that people in gene-

History.

ral of the industrious classes are in prosperous, or at least in comfortable circumstances. When that is not the case, as for some years previous to 1830 there is reason to apprehend it was not in this country, there will be a corresponding increase in the general mortality, which will not sensibly affect the general mass of persons on whose lives annuities and reversions or assurances depend.

In many cases of insurance, the managers who choose the lives know very little more about them than is stated by themselves or the medical attendants they refer to, and frequently they depend much on the reports of their agents in the country; but where they are in daily habits of intercourse with most of the persons whose lives they insure, or else in habits of intimacy with some who are so, they have the means of making a much better selection. That is stated to be the case with one of the London offices, and in which, accordingly, there is said to have been observed a remarkably small mortality.

For the reasons assigned above, it appears, that although lives carefully selected, with the advantage of the necessary facilities, and unmixed with others, may be considerably better than the general average, those on which annuities and assurances are granted are not, on the average, likely to be much better.

This part of the subject is also adverted to at the end of the article on the LAW of MORTALITY.

The two following Tables, A and B, show the number of Years' Purchase Annuities on Lives of different ages are worth in present money, according to MORE CORRECT Tables of Mortality.

Explanation of Table A.

The sign (+) after the number of lives and of deaths in column *a* signifies that the real number was greater than is there stated. Those stated were the numbers of the nominees in the two tontines which commenced in 1689 and 1696, the particulars of which have been given by M. Deparcieux; but he also made all the use he could of the tontine which commenced in 1734 (less than eight years before his observations terminated), without stating any of the numbers in his essay. And whatever may have been the whole number of nominees, or of their deaths, which he availed himself of in this tontine, M. Deparcieux's observations were actually made on so many more than 9260 nominees, and 7933 deaths, among them.

The number of persons living in the two Carlisle parishes at the end of the observations was 8677; but besides them, the observations were made upon the 1840 persons who died in the place in the term of nine years during which they were continued; and these numbers together amount to 10,517, the greatest number stated in column *b*. But the real number the observations were made upon was greater still, by the number who left the place and did not return during the observations, which is the reason of the mark (+) being put after 10,517 in column *b*.

For information respecting the number of lives insured, and of deaths, in the Equitable Assurance Society, given at the head of column *c*, the reader is referred to the note at the end of this historical introduction.

The better to enable the reader to judge of the comparative extent of the observations made upon the nominees in tontines, and other annuitants, by M. Deparcieux and Mr Finlaison, and of those made upon the population of the two Carlisle parishes, the lives insured in the Equitable Society, and the population of Sweden and Finland, the mean number of living annuitants has been assumed to have been an arithmetical mean proportional between the numbers of them at the commencement and at the end of the term, which can only be precisely true if they died off by equal numbers in equal times; and that is the reason why the double sign (±) has been placed after the mean number of the nominees or other annuitants in each column. Thus 2860± in column *d* shows that the mean number of living nominees of that description was 2860 *more or less*. The deviation from precision in this case is of no importance.

The values in column *a* have been taken from the work on Annuities of Mr Baron Maseres; those in columns *d* and *e* from Mr Finlaison's report (obs. 4 and 5); that in column *f* at each age to 50 inclusive is a mean between those in columns *d* and *e*;—after 50 they are taken from Mr Finlaison's 5th observation. The value in column *g* at each age is a mean between the two against the same age in columns *e* and *f* of table B; the values in column *i* are from Mr Finlaison's first observation.

Of Table B.

The values in columns *e* and *f* have been taken from the 20th and 13th observations respectively in Mr Finlaison's report, and were calculated from the rates of mortality for the two sexes, which have been adopted for use by government.

They were deduced from observations on the mortality among the nominees in the three Irish tontines which commenced in 1773, 1775, and 1778 respectively, on the tontine of 1789, and those of the sinking fund from 1808 to 1822.

It will be observed that the excess of the value of an annuity on a female life above that of a male is, according to the table for Sweden, in many cases not half, and in some less than one third as much as according to Mr Finlaison's, derived from the government annuitants. The cause of this cannot but be an object of interest, and deserves further investigation. It may arise in great measure from the ages of many females being stated below the truth in the Swedish returns, while they were accurately ascertained among the government annuitants.

Of Tables M, N, *and* O.

The values according to Demoivre's hypothesis were taken from Dodson's *Mathematical Repository* (vol. ii. p. 169); those in column *d* of table M, founded upon Duvillard's table of mortality for France before the Revolution, published in his work on the *Mortality from Small-Pox* (4to, Paris, 1806), were taken from *The Doctrine of Compound Interest* by M. Corbaux (8vo, London, 1825); the values according to Dupré and St Cyran from the *Calculs des Rentes Viagères* of the latter.

The authorities for the rest appear sufficiently from the preceding historical sketch.

The values of annuities according to M. Kersseboom's table of mortality are not given here, that table being of doubtful character, as he neither published the whole of the *data* from which he formed it, nor explained the manner of its construction.

It would have been desirable to include the values according to the tables of Dr Halley for Breslaw, and Dupré de St Maur for the Parisian and French country parishes in table M; but as the values of annuities have not been calculated from these tables at four *per cent.*, we have added tables N and O, and have given in each of them the values from the Northampton table, with the view of facilitating the comparison of the values in N and O with those in M and A.

Observations on the above Tables.

All the tables of mortality from which the values of annuities in tables M, N, and O, have been deduced, were calculated from *bills of mortality alone* of places where the population was variable, and the numbers of the people at the different ages were not ascertained. And therefore, notwithstanding the attempts to supply their defects, which were made by the eminent mathematicians who constructed them, none of them represented truly the laws of mortality in the places where the respective observations were made; as will be evident to those who understand the article on the *Law of Mortality* in this work, and pay the necessary attention to the materials and manner of construction of those tables. Consequently the values of annuities derived from them cannot be correct, but will in general be considerably less than the truth, even for the general average of the whole population of the places in which the observations were made.

But those values of annuities are also objectionable on this ground—that the places they were intended for, and understood to be adapted to, were generally populous towns, containing a large proportion of poor persons dependent upon their daily labour for their supply of food from day to day, often with little forethought, and many of them engaged in unwholesome employments, amongst whom great distress is often endured by the comparatively high prices of bread and potatoes, or the low rate of wages, when the unwholesome and scanty food they are reduced to produces typhus fever, and sometimes the dysentery among them, which carry them off in great numbers And these visitations were much more common at the times when the observations were made from which most of those tables were constructed, than they have been of late years.

None of those causes of mortality operate sensibly upon the general average of those persons upon whose lives leases or annuities, and reversions or assurances, depend, they being generally in the higher and middle classes. Neither do they produce much effect among the more deserving persons in the lower class, such as the members of friendly societies, and others who are both industrious and frugal enough to live within their incomes; nor indeed upon any who are in comfortable circumstances.

Hence it follows that the values of life-annuities, and, consequently, those of any pecuniary interests dependent upon the continuance or the failure of human life, cannot be correctly determined from observations made on a whole population similar to those of the places these tables were constructed from.

But this was not distinctly seen till of late years, and appears to be very imperfectly understood at present (in the year 1830), even by some who might be expected to possess correct information on the subject.

The tables constructed by Dr Price, both from the Swedish observations, and those made by Dr Haygarth at Chester, threw valuable light on this subject. But deficient crops in Sweden operate powerfully in raising the mortality there, in comparison with the more fruitful parts of Europe; therefore, the values of annuities copied into table B, and col. *h* of table A, from Dr Price's work, must only be understood as sufficiently correct for the period and place in which the observations were made. And the Chester table is in some degree liable to the same objections as the others above mentioned.

On Table A.

For nearly 70 years after its publication, M. Deparcieux's table, from which the values given in col. *a* of table A were derived, was the only one from which the values of life-interests and of reversions depending upon lives could be determined with considerable accuracy. But the comparatively high values of annuities according to that table were always supposed to arise from the careful selection of the lives; notwithstanding that they were almost all inhabitants of Paris and its environs.[1] At that time (1689–1696) the Parisians were much worse lives than during the last 50 years, and a judicious selection was much less likely to be made then than now.

It is to be regretted that the Carlisle observations were only continued nine years, commencing with 1779; but the less so since Mr Milne has shown in his work on annuities (p. 429), that during the term of 22 years commencing with 1779, the proportion of the annual average number of deaths to the mean number of the people was the same as in these first nine years, viz. that of 1 to 40.

In comparing the values in column *c* of table A with the rest, it should be borne in mind that a great majority of insured lives are males, on which account the values are somewhat lower, especially from 15 to 55 years of age, than they would have been had there been nearly equal numbers of both sexes.

Columns *d* and *e* are very instructive. In the session of 1789, an act (29 Geo. III. cap. 41) was passed for raising the sum of L.1,002,500 by the sale of shares in a tontine; but the scheme did not succeed, the persons who in the first instance had taken the whole of the shares with the expectation of selling them at a profit not having been able to dispose of half of them; and to afford those persons relief, an act (30 Geo. III. cap. 45) was passed in the next session, allowing them, before the 20th September of that year (1790), to exchange each of the tontine shares they had not been able to dispose of, for an annuity-certain payable during $69\frac{1}{4}$ years. And in order that those who had taken shares, and fixed upon their nominees in the tontine, might be placed in the same situation with regard to the benefit of survivorship as if the scheme had completely succeeded, this act empowered the commissioners of the treasury to select tontine nominees for the exchanged shares, from *the Peers of Great Britain and Ireland, their children or grandchildren; baronets, lords of manors, justices of the peace in England and Wales, or their children; the dignitaries of the church or beneficed clergy, fellows of colleges, the governors of the Charter House, the Foundling Hospital, or Christ's Hospital, and those who were registered in the books of the Amicable Life Assurance Society.*

The commissioners of the treasury were to distribute their nominees into six classes according to their ages, in proportion to the nominees of the contributors in the same classes. Tickets with the names of the nominees were then to be put into six boxes, set apart for the respective classes, and drawn out till a sufficient number to complete the tontine was obtained for each class. All of which was performed accordingly.

The values of annuities on the lives chosen by the contributors are given in col. *d*, on those thus drawn by lot in col. *e*, and the two combined in col. *f*.

Thus it appears that, of the lives in col. *e*, there was no selection except their being taken from the descriptions of persons above mentioned, who were all in the upper or middle classes of society. But, as might have been anticipated, a considerable majority of female lives were chosen by the contributors, and a considerable majority of males were drawn by the commissioners of the treasury, the descriptions of persons they were restricted to, consisting principally of males.

It will be observed that the values in columns *d* and *e* agree very nearly:—they would probably have agreed better still had the proportion of the two sexes been the same in both.

And this shows how little advantage the contributors derived from choosing their nominees, beyond what was secured to them by the classes of society they were selected from.

The values of annuities in column *i* are much less than in any other of table A; they are even less than those derived from the Northampton table of mortality.

But it would be equally precipitate and unphilosophical to conclude from thence, without further investigation, that the bulk of the people of England 100 years ago were so much shorter lived than they are now.

That the prolongation of life among the bulk of the population, from and after every age, has been very considerable during the last century, no unprejudiced person who has paid sufficient attention to the subject to qualify himself for judging of it can entertain a doubt; or that it has also been somewhat lengthened among the upper and middle classes of society; but not nearly to the extent which a comparison of columns *g* and *i* of table A would seem to imply.

There is certainly no rational ground for supposing that the physical constitution of man has altered: any change that has taken place can only have been produced by changes in the habits of the people, and the circumstances in which they have been placed.

All this might have been reasonably concluded in the absence of further information; but an examination of the circumstances under which the tontine of 1693 was

[1] As M. Deparcieux states in his *Essai*, p 62.

formed, and of the first observation in Mr Finlaison's report, from which the values in col. *i* have been deduced, will confirm it.

In that year, the same in which Dr Halley's paper on the Breslaw Bills was published in the *Philosophical Transactions*, this branch of knowledge was in its infancy. By the 22d section of the act (4 William and Mary, cap. 3) for raising a million of money by the sale of shares in this tontine, it was enacted that, if the sale of the tontine shares did not produce the whole sum wanted by the first of May 1693, then between that day and the 29th September following, for any sum contributed towards the completion of the million, the contributor should receive 14 *per cent. per annum* on such sum during the life of any person he might choose to nominate; the common interest of money at that time being 6 *per cent. per annum*. And by an act passed in the next session (5 William and Mary, cap. 5), the term for granting annuities on these terms, and for the same purpose, was extended to the 1st of May 1694. This was selling annuities at half their true value.

The age of a nominee is never mentioned in either of these acts, and those in the tontine were not distinguished into classes. These things were, at the same time, managed better in France.

Even Dr Halley was not aware of the greater mortality of males, and the consequent greater proportion of females in the population, as appears by his paper above mentioned; for after calculating from his table of mortality the number of inhabitants in Breslaw between 18 and 56 years of age to be 18,053, he says, " at least one half of these are males."

The contributors to the tontine could not be expected to be better informed on these subjects than the parliament and Dr Halley; and, with respect to ages and sexes, the following appears by Mr Finlaison's statement to have been their selection of nominees.

Aged.	Number of		
	Males.	Females.	Both.
Under 6	178	113	291
Between 6 and 11	178	118	296
Under 11	356	231	587
Between 11 and 16	119	96	215
Under 16	475	327	802
Between 16 and 21	49	39	88
Under 21	524	366	890
Above that age	70	42	112
Total	594	408	1002

In the absence of better information, it would seem reasonable to conclude that the younger a life was, the longer it would be likely to last; and accordingly we find that more than half the lives were under 11 years of age at the time of their nomination. And as males are more robust than females, it was also natural to conclude that a less rate of mortality would prevail among them; and accordingly three fifths of the nominees were males.

But subsequent observations have shown that, in both instances, the contributors made a bad choice.

Besides, of all the nominees, only one ninth had completed their 21st year at the time of their nomination. Not only the constitutions of these young nominees were not then fully formed or developed, but the mortality among them would depend greatly upon their destiny in after-life, or the circumstances of their respective situations, and upon their moral conduct: all of which must be very uncertain, and difficult to judge of at such early ages.

It is not improbable, too, that, on account of their beauty and healthy appearance, many children of scrofulous constitutions were selected; and they, on an average, would be short-lived.

It is probable that a great majority of the contributors, and therefore of their nominees, resided in London or other large and crowded towns, which have always been peculiarly unfavourable to the health of children, but were much more so then than they are now.

All circumstances considered, there appears sufficient evidence to show that the mortality among these nominees must have been much greater than among the general average of selected lives, or the general average of the people in comfortable circumstances at that time; and that, if the nominees in the English tontine of 1693 had been distributed into classes according to their ages, and a larger annuity for the same purchase-money had been allowed to the older classes, always with benefit of survivorship, the lives would have been more judiciously chosen, and would not probably have differed materially from the nominees in the French tontines of 1689 and 1696, which M. Deparcieux's observations were made upon,—they, it has been shown, were but little inferior in goodness to our present annuitants and insured lives.

The values of annuities on single lives given in Mr Finlaison's report are only specimens at one rate of interest of the results of calculations made at several rates. And extensive calculations have also been made at the Government Life-Annuity Office, of the values of annuities on two and on three joint lives, with distinction of the sexes. But none of these have been published, nor do they now (in July 1830) at that office grant any annuity depending upon more than one life, nor expect to do so for two or three years to come.

In this country, cases are continually occurring, in which an equitable adjustment of the rights and interests of different parties in property depending upon the continuance or the failure of human life, is of great importance; and in many cases it cannot be made with sufficient accuracy without tables of the values of all possible combinations of two and even of three joint lives of different ages and of both sexes. But not unfrequently, especially in cases of contingent reversions, we have been hitherto, and are still, obliged to use approximations to the values of all the possible combinations of the lives involved, not only with each other, but also of them with others one year younger than each of them respectively. In these cases it sometimes happens that the whole value sought, being but a small part of a year's purchase, is less than the probable error of several of these approximations considered separately; and then it is very difficult to give with confidence even a near approximation to the value sought.

But in a great many other cases of frequent occurrence and less difficulty, the want of a complete set of good tables of this kind is much felt. It is therefore highly desirable that, numerous calculations for them having been made at the expense of the public, they should be completed at the public expense, and rendered accessible to persons having occasion to use them; by printing, if the expense would not be too great; otherwise, by having several manuscript copies accurately made, and deposited in convenient places for inspection, upon payment of a small fee.

A few writers on these subjects, of late years, have employed the differential and integral calculus in their in-

History. vestigations. We have not yet seen any fruits of this application of the calculus which appear to us of much value, nor are we at all sanguine in expecting any.

Although Lambert and Duvillard had made some efforts in this way before, Laplace (in his *Théor. Anal. des Probabilités*, No. 40) was the principal writer who thus treated the subject, and that very shortly, merely touching upon the elements. He arrived in the usual manner at the same formulæ that are given in the elementary algebraic method, and are here demonstrated by common arithmetic; only expressed in the manner of the higher calculus, in terms of the absciss and ordinate of the curve of mortality, both considered as variable quantities.

He judiciously observed that the integral might be obtained in every case by calculating all its terms from a table of mortality, and taking their sum; and that in this manner tables of the values of annuities on single and joint lives might be calculated; which is only reverting to the usual method.

But he also observed that the same thing might be effected by describing a parabolic curve through the vertices of the two extreme and several intermediate ordinates of the curve of mortality, and even that a few of these would be sufficient, since the differences between the different tables of mortality would justify us in considering that method to be equally exact with those tables themselves. And in this we should entirely concur with that profound mathematician, provided we could admit that those tables, or most of them, had equal titles to our confidence, which he appears tacitly to assume.

But here it is that M. Laplace appears to us to have fallen into the same error as most others respecting those tables of mortality, from not having paid sufficient attention to the data they were constructed from, and the manner of their construction.

After what has been advanced in this article, and in that on the *Law of Mortality* in this work, we think it quite unnecessary to say more here, than that we consider it an History. established truth, that tables of mortality well constructed from proper *data*, for determining the values of annuities and reversions, do not differ materially from each other.

If imperfect data for constructing a table of mortality be obtained, and any one already constructed, or the mean of several of them, be taken as a pattern or standard, to which it is desired that the new table should approach, it will not be difficult, by the known methods of approximation and interpolation, so to construct such new table that it shall not differ much from the standard; but such new table, being in a certain degree hypothetical, can be of little or no value.

According to the usual methods of treating these subjects, and constructing accurate tables, we never depart from the observations, but are supported by them at every step: our clear and simple methods of reasoning and calculation are much superior to the data we can obtain: proper data are alone wanting to further the science at present; government only can effectually supply them, and all who take any interest in these subjects must be grieved to find that there is little or no hope of assistance from that quarter. Even if a wiser course be adopted in future, 20 years more must elapse before we can reap the benefit of it.

This is not the proper place to enter further into that part of the subject; but to those who take an interest in it, we would recommend the perusal of the minutes of evidence taken before the committee on the population bill, ordered by the House of Commons to be printed 11th May 1830; and the minutes of the committee on the recommitted bill, printed 26th May 1830; especially, in the latter, Mr Milne's letter to Mr Davies Gilbert, the chairman, in answer to an application made to him for his opinion, with Mr Rickman's marginal notes on that letter, and his observations on it in *his* letter to the chairman, which Mr Milne knew nothing of till the bill was passed.

NOTE REFERRED TO IN TWO PLACES ABOVE.

According to Mr Morgan's statements in the places here referred to, the number of members, or of assurances, or of policies, found to be in the Equitable Assurance Society, was—

At the end of the year			Reference to Mr Morgan's Statement.
1768	564	Policies	View of Rise and Progress, &c. p. 10.
1770	490	Policies	Ditto ... ditto.
1772	500+	Members	Ditto ... p. 27.
1773	734	Members	Address of 7th March 1793 ... p. 118.[1]
1776	913	Policies	Ditto of 24th April 1800 ... p. 140.
1783	1608	Members	Ditto of 7th March 1793 ... p. 118.
1786	2100+	Members	Ditto of 24th April 1800 ... p. 140.
1792	4640	Assurances	View of Rise and Progress, &c. p. 24.
1799	5124	Members	Ditto ... p. 26.

From which we infer, that if, at the end of each year, beginning with 1770, and ending with 1799, the number had been taken, the sum of all the 30 would have been 75,664, and the mean number during these 30 years 2522.

In a note on p. 443, vol. ii. of Dr Price's *Obs. on Rev. Paym.* (7th edit.), Mr Morgan states, that during 33 years, from January 1768 to January 1801, the number of assurances on single lives had been 83,201; but this great number can only be the sum of the 33 annual numbers as above mentioned, and the mean of these will be 2521.

What we wish to know is, the mean number of lives insured on which policies were in force during the observations; but that Mr Morgan never mentions. As more policies than one are not unfrequently granted for so many distinct assurances on the same life, neither the number of policies nor of assurances will answer our purpose; neither will the number of members, for if a policy be granted to A for insurance on the life of B, A is the member of the society, and not B, who is only the life assured, and several other members besides A may insure the life of B, while A may also hold more policies than one insuring B's life.

As has been already observed, Mr Morgan has repeatedly stated that the rate of mortality in the Equitable Society has always continued the same. And by tables *a* and *b* it appears, that out of 91,512 living persons in a similar society above 20 years of age, 1489 would die annually; also, in the table at the end of Mr Morgan's annuities (2d ed.), it is stated, that during the first 20 years of the 19th century, 1923 of the lives assured in the society died above 20 years of age; but 1489 : 1923 :: 91,512 : 118,185, so that this last is the number of lives in a similar society, out of which these 1923 deaths would happen in one year.

[1] These addresses are printed at the end of the deed of settlement of the society, for the use of the members: the copy quoted from was printed in 1801.

History.

Then supposing, what is probably near the truth, that under 10 years of age the number of policies was the same as that of the lives insured, we shall have, by the statement last mentioned,

	Number of Lives.	Number of Annual Deaths.
Between 10 and 20 years of age	1,494	7
Above 20	118,185	1923
Above 10 years of age	119,679	1930

And $\frac{119,679}{20} = 5984$ is the mean number above 10.

That is, a population falling short of 6000, instead of exceeding 150,000, as stated by Mr Morgan.

But by the table above mentioned in Mr Morgan's work on annuities, and the explanations of it given above, it appears that by 151,754 policies in force in the society,
119,679 lives were insured;
and 119,679 : 151,754 :: 7 : 9 nearly (more nearly :: 11 : 14). So that the number of lives was to that of the policies as 7 to 9 nearly, during the twenty years ending with 1820

On p. 61 of his pamphlet *On the Rise and Progress of the Equitable Society*, Mr Morgan states the proportion in 1827 to have been that of 3 to 4 nearly; and from another statement of his in a note on p. 42 of the same pamphlet, it would appear to have been that of 5 to 6 during the 12 years ending with 1827. The proportion above stated is nearly a mean between these two.

Taking the mean number of lives on which assurances were in force in the Equitable Society during the last 30 years of the eighteenth century to have been 2522, as determined above; since 119,679 : 2522 : : 1930 : 40·671, this last is the annual average number of deaths in the society during these 30 years; therefore the whole number of them must have been 1220, which being added to 5124, the greatest number living at any one time during the term (that is, at the end of 1799, as stated above), the sum is 6344. And the greatest number of lives on which Mr Morgan's observations were made during that term must have exceeded this, by the number who went out of the society by sale or forfeiture of the assurances, or by the expiration of the limited terms some of them were granted for, and did not enter it again; wherefore the sign (+) is added as before in table A.

In treating of Annuities, we think that it may be useful in a work of this kind to address ourselves as well to those readers who have not, as to those who have, an acquaintance with *Algebra;* and we shall accordingly divide what follows into two Parts, corresponding to these two views of the subject.

PART I.

We shall in this Part demonstrate all that is most useful and important in the doctrine of annuities and assurances on lives, without using algebra or introducing the idea of probability; but the reader is of course supposed to understand common arithmetic. In the first 30 numbers of this Part, *compound interest* and *annuities-certain* are treated of; from the 31st to the 76th the doctrine of *annuities on lives* is delivered; and that of *assurances* on lives from thence to the 108th, where the popular view terminates.

What is demonstrated in this Part will be sufficient to give the reader clear and scientific views of the subjects treated, and, with the assistance of the necessary tables, will enable him to solve the more common and simple problems respecting the values of annuities and assurances. He will also understand clearly the general principles on which problems of greater difficulty are resolved; but these he cannot undertake with propriety when the object is to make a fair valuation of any claims or interests, with a view to an equitable distribution of property, unless he has studied the subject carefully, with the assistance of algebra; for intricate problems of this kind can hardly be solved without it; and those who are not much exercised in such inquiries often think they have arrived at a complete solution, while they have overlooked some circumstance or event, or some possible combination of events or circumstances, which materially affects the value sought. Eminent mathematicians have in this way fallen into considerable errors, and it can hardly be doubted that those who are not mathematicians must (*cæteris paribus*) be more liable to them.

I.—On Annuities-Certain.

No. 1 When the rate is 5 *per cent.*, L.1 improved at simple interest during one year will amount to L.1·05; which, improved in the same manner during the second year, will be augmented in the same ratio of 1 to 1·05: the amount then will therefore be $1·05 \times 1·05$, or $(1·05)^2 = 1·1025$.

In the same manner it appears that this last amount, improved at interest during the third year, will be increased to $(1·05)^3 = 1·157625$; at the end of the fourth year it will be $(1·05)^4$; at the end of the fifth $(1·05)^5$, and so on; the amount at the end of any number of years being always determined by raising the number which expresses the amount at the end of the first year to the power of which the exponent is the number of years. So that when the rate of interest is 5 *per cent.*, L.1 improved at compound interest will in seven years amount to $(1·05)^7$, and in 21 years to $(1·05)^{21}$.

But if the rate of interest were only 3 *per cent.*, these amounts would only be $(1·03)^7$ and $(1·03)^{21}$ respectively.

2. The present value of L.1 to be received certainly at the end of any assigned term, is such a less sum as, being improved at compound interest during the term, will just amount to one pound. It must therefore be less than L.1, in the same ratio as L.1 is less than its amount in that time; but in three years at 5 *per cent.* L.1 will amount to L.$(1·05)^3$ (1). And $(1·05)^3 : 1 :: 1 : \frac{1}{(1·05)^3}$, so that $\frac{1}{(1·05)^3} = \frac{1}{1·157625} = 0·863838$ is the present value of L.1 to be received at the expiration of three years.

In the same manner it appears that, at 4 *per cent.* interest, the present value of L.1 to be received at the end of a year is $\frac{1}{1·04} = 0·961538$; and if it were not to be received until the expiration of 21 years, its present value would be $\frac{1}{(1·04)^{21}} = (0·961538)^{21} = 0·438834$.

Hence it appears, that if unit be divided by the amount of L.1 improved at compound interest during any number of years, the quotient will be the present value of L.1 to be received at the expiration of the term; which may also be obtained by raising the number which expresses the present value of L.1 receivable at the expiration of a year, to the power of which the exponent is the number of years in the term.

Popular View.

3. When a certain sum of money is receivable annually, it is called an *Annuity*, and its *quantum* is expressed by saying it is an annuity of so much; thus, according as the annual payment is L.1, L.10, or L.100, it is called an annuity of L.1, of L.10, or of L.100.

4. When the annual payment does not depend upon any contingent event, but is to be made certainly, either in perpetuity or during an assigned term, it is called an *Annuity-certain*.

5. In calculating the value of an annuity, the first payment is always considered to be made at the end of the first year from the time of the valuation, unless the contrary be expressly stated.

6. The whole number, and part or parts of one annual payment of an annuity, which all the future payments are worth in present money, is called *the number of years' purchase* the annuity is worth, and, being the sum of the present values of all the future payments, is also the sum which, being put out and improved at compound interest, will just suffice for the payment of the annuity. (2.)

7. Hence it follows, that when the annuity is L.1, the number of years' purchase and parts of a year is the same as the number of pounds and parts of a pound in its present value.

And throughout this article, whenever the *quantum* of an annuity is not mentioned, it is to be understood to be L.1.

8. The sum of which the simple interest for one year is L.1, is evidently that which, being put out at interest, will just suffice for the payment of L.1 at the end of every year, without any augmentation or diminution of the principal, and, being equivalent to the title to L.1 *per annum* for ever, is called the *value of the perpetuity*, or the number of years' purchase the perpetuity is worth.

But while the rate remains the same, the annual interests produced by any two sums are to each other as the principals which produce them; therefore, since $5 : 1 :: 100 : \frac{100}{5} = 20$, when the rate of interest is 5 *per cent.*, the value of the perpetuity is 20 years' purchase. In the same manner it appears, that according as the rate may be 3 or 6 *per cent.*, the value of the perpetuity will be $\frac{100}{3} = 33\frac{1}{3}$, or $\frac{100}{6} = 16\frac{2}{3}$ years' purchase; and may be found in every case, by dividing any sum by its interest for a year.

9. All the most common and useful questions in the doctrines of compound interest and annuities-certain may be easily resolved by means of the first four tables at the end of this article. Their construction may be explained by the following specimen, rate of interest 5 *per cent.*

CONSTRUCTION OF

Term.	Table IV. Amount of L.1 *per annum* improved at Interest until	Table III. Amount of L.1 improved at Interest until	Table I. Present value of L.1 to be received at	Table II. Present value of L.1 *per annum*, to be received until	Term.
	the Expiration of the Term.				
1 yr.	1·000000	1·050000	·952381	0·952381	1 yr.
2 yrs.	2·050000	1·102500	·907029	1·859410	2 yrs.
3	3·152500	1·157625	·863838	2·723248	3
4	4·310125	1·215506	·822702	3·545950	4
5	5·525631	1·276282	·783526	4·329476	5
6	6·801913	1·340096	·746215	5·075691	6
7	8·142009	1·407100	·710681	5·786372	7

10. The calculation must begin with Table III., the first number in which should evidently be 1·05, the amount of L.1 improved at interest during one year, which being multiplied by 1·05, the product is 1·025, the second number. This second number being multiplied by 1·05, the product is 1·157625, the amount at the end of three years. And so the calculation proceeds throughout the whole of the column; each number after the first being the product of the multiplication of the preceding number, by the amount of L.1 in a year. (1.)

11. The number against any year in Table I. is found by dividing unit by the number against the same year in Table III. (2); thus, the number against the term of six years in Table I. is $\frac{1}{1{\cdot}340096} = {\cdot}746215$. All the numbers in that table after the first may also be found by multiplying that first number continually into itself. (2.)

12. The number against any year in Table II., being the sum of the numbers against that and all the preceding years in Table I., is found by adding the number against that year in Table I. to the number against the preceding year in Table II.; thus, the number against four years in Table II. being

the sum of 0·822702
and 2·723248

is 3·545950.

13. If each payment of an annuity of L.1 be put out as it becomes due, and improved at compound interest during the remainder of the term, it is evident that at the expiration of the term the payment then due will be but L.1, having received no improvement at interest. That received one year before will be augmented to the amount of L.1 in a year; that received two years before will be augmented to the amount of L.1 in two years; that received three years before to the amount of L.1 in three years; and so on until the first payment, which will be augmented to the amount of L.1 in a term one year less than that of the annuity.

Hence it is manifest that the number against any year in Table IV. will be unit added to the sum of all those against the preceding years in Table III.

And therefore that the number against any year in Table IV. is the sum of those in Tables III. and IV. against the next preceding year.

Thus, the number against seven years in Table IV. being

the sum of 1·340096
and 6·801913

is 8·142009.

14. The method of construction is obviously the same at any other rate of interest.

15. All the amounts and values which are the objects of this inquiry evidently depend upon the improvement of money at compound interest; it is therefore, that the first, second, and fourth tables, all depend upon the third.

But every pound, and every part of a pound, when put out at interest, is improved in the same manner as any single pound considered separately. Whence it is obvious, that while the term and the rate of interest remain the same, both the amount and the present value, either of any sum or of any annuity, will be the same multiple, and part or parts of the amount or the present value found against the same term, and under the same rate of interest in these tables, as the sum or the annuity proposed is of L.1.

So that to find the amount or the present value of any sum or annuity for a given term and rate of interest, we have only to multiply the corresponding tabular value by

Popular View.

the sum or the annuity proposed; the product will be the amount or the value sought, according as the case may be.

16 *Example* 1. To what sum will L.100 amount when improved at compound interest during 20 years, the rate of interest being 4 *per cent. per annum?*

By Table III. it appears that L.1 so improved would, at the expiration of the term, amount to L.2·191123; therefore L.100 would amount to 100 times as much, that is, to L.219·1123, or L.219. 2s. 3d.

17. *Ex.* 2. What is the present value of L.400, which is not to be received until the expiration of 14 years, when the rate of interest is 5 *per cent.?*

The present value of L.1 to be received then will be found by Table I. to be L.0·505068: L.400 to be received at the same time will therefore be worth, in present money, 400 times as much, or L.202·0272, that is, L.202. 0s. $6\frac{1}{2}$d.

18. *Ex.* 3. Required the present value of an annuity of L.50 for 21 years, when the rate of interest is 5 *per cent.*

Table II. shows the value of an annuity of L.1 for the same term to be L.12·8212; the required value must therefore be 50 times as much, or L.641·06, that is L.641. 1s. $2\frac{1}{2}$d.

19. *Ex.* 4. What will an annuity of L.10. 10s. or L.10·5 for thirty years amount to, when each payment is put out as it becomes due, and improved at compound interest until the end of the term; the rate of interest being 4 *per cent.?*

The amount of an annuity of L.1 so improved would be L.56·084938, as appears by Table IV.; the amount required will therefore be 10·5 times this, or L.588·89185, that is L.588. 17s. 10d.

20. When the interval between the time of the purchase of an annuity and the first payment thereof exceeds that which is interposed between each two immediately successive payments, such annuity is said to be *deferred* for a time equal to that excess, and to be *entered upon* at the expiration of that time.

21. If two persons, *A* and *B*, purchase an annuity between them, which *A* is to enter upon immediately, and to enjoy during a certain part of the term, and *B* or his heirs or assigns for the remainder of it, the present value of *B's* interest will evidently be the excess of the value of the annuity for the whole of the term from this time, above the value of the interest of *A*.

So that when the entrance on an annuity is deferred for a certain term, its present value will be the excess of the value of the annuity for the term of delay and continuance together, above the value of an equal annuity for the term of delay only.

22. *Example* 1. Required the value of a perpetual annuity of L.120, which is not to be entered upon until the expiration of 14 years from this time, reckoning interest at 3 *per cent.*

The perpetuity, with immediate possession, would be worth $33\frac{1}{3}$ years' purchase (8); and an annuity for the term of delay is worth 11·2961 (Table II.)

From	33·3333
subtract	11·2961, and multiply
the remainder	22·0372
by	120
the product,	2644·464 = L.2644. 9s. $3\frac{1}{4}$d.,

is the required value.

23. *Ex.* 2. Allowing interest at 5 *per cent.*, what sum should be paid down now, for the renewal of 14 years lapsed in a lease for 21 years of an estate producing L.300 *per annum*, clear of all deductions?

This is the price of an annuity for 14 years, to be entered upon 7 years hence; the term of delay, therefore, is 7 years, and that of the delay and continuance together 21 years.

By Table II. it appears, that the present value of an annuity

for 21 years, is	12·8212	years' purchase.
for 7 years,	5·7864	
Value of the deferred annuity,	7·0348	
Multiply by	300	
The product,	L.2110·44, or L.2110. 8s. $9\frac{1}{2}$d.,	

is the price required.

24. Hitherto we have proceeded upon the supposition of the annuity being payable, and the interest convertible into principal, which shall reproduce interest, only once a year.

But annuities are generally payable half yearly, and sometimes quarterly; and the same circumstances that render it desirable for an annuitant to receive his annual sum in equal half-yearly or quarterly portions, also give occasion to the interest of money being paid in the same manner.

But whatever has been advanced above concerning the present value or the amount of an annuity, when both that and the interest of money were only payable once a year, will evidently be true when applied to half the annuity and half the interest paid twice as often, on the supposition of half-yearly payments; or to a quarter of the annuity and a quarter of the interest paid four times as often, when the payments are made quarterly.

25. Half-yearly payments are, however, by far the most common; and these four tables will also enable us to answer the most useful questions concerning them.

For we have only to extract the present value, or the amount, from the table, against twice the number of years in the term, at half the annual rate of interest, and, in the case of an annuity, to multiply the number so extracted by half the annuity proposed.

26. *Ex.* 1. To what sum will L.100 amount in 20 years, when the interest at the rate of 4 *per cent. per annum* is convertible into principal half-yearly?

This being the amount in 40 half years at 2 *per cent.* interest for every half year, will be the same as the amount in 40 years at 2 *per cent. per annum*, which, by Table III. will be found to be 220·804, or L.220. 16s. 1d.; and is only L.1. 13s. 10d. more than it would amount to if the interest were not convertible more than once a year. (16.)

27. *Ex.* 2. What is the present value of an annuity of L.50 for 21 years, receivable in equal half-yearly payments, when money yields an interest of $2\frac{1}{2}$ *per cent.* every half year?

By Table II. it appears, that an annuity of L.1 for 42 years, when the interest of money is $2\frac{1}{2}$ *per cent. per annum*, will be worth L.25·8206 (25); 25 times this sum, or L.645. 10s. $3\frac{1}{2}$d., is therefore the required value, and exceeds the value when the interest and the annuity are only payable once a year, by L.4. 9s. 1d. (18.)

28. The excess of an annuity-certain above the interest of the purchase-money, is the sum which, being put out at the time of each payment becoming due, and improved at compound interest until the expiration of the term, will just amount to the purchase-money originally paid.

But, while every thing else remains the same, the longer the term of the annuity is, the less must its excess above the interest of the purchase-money be, because a less annuity will suffice for raising the same sum within the term. Therefore, the proportion of that excess to the annual interest of the purchase-money continually diminishes as

the term is extended; and when the annuity is a perpetuity, there is no such excess. (8.)

29. The reason why the value of an annuity is increased by that and the interest being both payable more than once in the year, is, that the granter loses and the purchaser gains the interest produced by that part of each payment which is in excess above the interest then due upon the purchase-money, from the time of such payment being made until the expiration of the year.

Hence it is obvious, that the less this excess is, that is, the longer the term of the annuity is (28), the less must the increase of value be.

And when the annuity is a perpetuity, its value will be the same, whether it and the interest of money be both payable several times in the year, or once only.

30. When the annuity is not payable at the same intervals at which the interest is convertible into principal, its value will depend upon the frequencies both of payment and conversion; but its investigation without algebra would be too long, and of too little use, to be worth prosecuting here.

II.—Of Annuities on Lives.

31. When the payment of an annuity depends upon the existence of some life or lives, it is called a *Life-Annuity.*

32. The values of such annuities are calculated by means of tables of mortality, which show, out of a considerable number of individuals born, how many upon an average have lived to complete each year of their age, and, consequently, what proportion of those who attained to any one age have survived any greater age.

The fifth table at the end of this article is one of that kind which has been taken from Mr Milne's *Treatise on Annuities,* and was constructed from accurate observations made at Carlisle by Dr Heysham, during a period of nine years, ending with 1787.

33. By this table it appears, that during the period in which these observations were made, out of 10,000 children born, 3203 died under five years of age, and the remaining 6797 completed their fifth year. Also, that out of 6797 children who attained to five years of age, 6460 survived their tenth year.

But the mortality under ten years of age has been greatly reduced since then by the practice of vaccination.

This table also shows, that of 6460 individuals who attained to 10 years of age, 6047 survived 21; and that of 5075 who attained to 40, only 3643 survived their 60th year.

34. There is good reason to believe (as has been shown in another place) that the general law of mortality, that is, the average proportion of persons attaining to any one age, who survive any greater age, remains much the same now among the entire mass of the people throughout England, as it was found to be at Carlisle during the period of these observations, except among children under ten years of age, as was noticed above. (33.)

If this be so, it will follow, that of 6460 children now 10 years of age, just 6047 will attain to 21; or rather, that if any great number be taken in several instances, this $\left(\frac{6047}{6460}\right)$ will be the average proportion of them that will survive the period.

And if 6460 children were to be taken indiscriminately from the general mass of the population at 10 years of age, and an office or company were to engage to pay L.1 eleven years hence for each of them that might then be living, this engagement would be equivalent to that which should bind them to pay L.6047 certainly at the expiration of the term. Therefore the office, in order that it might neither gain nor lose by the engagement, should, upon entering into it, be paid for the whole, the present value of L.6047 to be received at the expiration of eleven years; and for each life the $\frac{1}{6460}$th part of it, that is, the $\frac{6047}{6460}$th part of the present value of L.1, to be received then.

But when the rate of interest is 5 *per cent.*, the present value of L.1, to be received at the expiration of 11 years, is L.0·584679; therefore, at that rate of interest, there should be paid for each life $\frac{6047 \times 0{\cdot}584679}{6460} = \text{L.}0{\cdot}5473.$

And the present value of L.100, to be received upon a life now 10 years of age attaining to 21, will be L.54·73, or L.54. 14s. 7d.

In the same manner it will be found, that reckoning interest at 4 *per cent.*, the value would be L.60. 16s. 1d.

35. This is the method of calculating the present values of endowments for children of given ages; and the values of annuities on lives may be computed in the same manner.

For, from the above reasoning it is manifest, that if the present value of L.1, to be received certainly at the expiration of a given term, be multiplied by the number in the table of mortality against the age, greater than that of any proposed life by the number of years in the term, and the product be divided by the number in the same table, against the present age of that life; the quotient will be the present value of L.1, to be received at the expiration of the term, provided that the life survive it.

And if, in this manner, the value be determined of L.1, to be received upon any proposed life, surviving each of the years in its greatest possible continuance, according to the table of mortality adapted to it; that is, according to the Carlisle table, upon its surviving every age greater than its present, to that of 104 years inclusive; then, the sum of all these values will evidently be the present value of an annuity on the proposed life.

36. If 5642 lives at 30 years of age be proposed, and 5075 at the age of 40; since each of the 5642 younger lives may be combined with every one of the 5075 that are 10 years older, the number of different pairs, or different combinations of two lives differing in age by 10 years, that may be formed out of the proposed lives, is 5642 times 5075.

But at the expiration of 15 years the survivors of the lives now 30 and 40 years of age, being then of the respective ages of 45 and 55, will be reduced to the numbers of 4727 and 4073 respectively; and the number of pairs, or combinations of two, differing in age by 10 years, that can be formed out of them, will be reduced from 5642×5075 to 4727×4073.

So that L.1 to be paid at the expiration of 15 years for each of these 5642×5075 pairs or combinations of two now existing, which may survive the term, will be of the same value in present money as 4727 times L.4073 to be received certainly at the same time.

Now, let A be any one of these lives of 30 years of age, and B any one of those aged 40; and, from what has been advanced, it will be evident that the present value of L.1, to be received upon the two lives in this particular combination jointly surviving the term, will be the same as that of the sum $\frac{\text{L.}4727 \times 4073}{5642 \times 5075}$ to be then received certainly.

But, when the rate of interest is 5 *per cent.*, L.1 to be received certainly at the expiration of 15 years, is equivalent to L.0·481017 in present money. (Table I.)

Therefore, at that rate of interest, and according to the Carlisle table of mortality, the present value of L.1 to be received upon A and B, now aged 30 and 40 years respectively, jointly surviving the term of 15 years, will be

$$\frac{4727 \times 4073 \times \text{L.}0{\cdot}481017}{5642 \times 5075}.$$

Popular View.

37. Hence it is sufficiently evident how the present value of L.1 to be received upon the same two lives jointly surviving any other year may be found. And if that value for each year from this time until the eldest life attain to the limit of the table of mortality be calculated, the sum of all these will be the present value of an annuity of L.1 dependent upon their joint continuance.

In this manner, it is obvious that the value of an annuity on the joint continuance of any other two lives might be determined.

38. If, besides the 5642 lives at 30 years of age, and the 5075 at 40 (mentioned in No. 36), there be also proposed 3643 at 60 years of age, each of these 3643 at 60 may be combined with every one of the 5642×5075 different combinations of a life of 30, with one of 40 years of age; and, therefore, out of these three classes of lives $5642 \times 5075 \times 3643$ different combinations may be formed, each containing a life of 30 years of age, another of 40, and a third of 60.

But at the expiration of 15 years the numbers of lives in these three classes will, according to the table of mortality, be reduced to 4727, 4073, and 1675 respectively; the respective ages of the survivors in the several classes being then 45, 55, and 75 years; and the number of different combinations of three lives (each of a different class from either of the other two) that can be formed out of them, will be reduced to $4727 \times 4073 \times 1675$.

Hence, by reasoning as in No. 36, it will be found, that if A, B, and C be three such lives, now aged 30, 40, and 60 years, the present value of L.1 to be received upon these three jointly surviving the term of 15 years from this time, will be $\frac{4727 \times 4073 \times 1675}{5642 \times 5075 \times 3643} \times \text{L.}0{\cdot}481017$: interest being reckoned at 5 *per cent.*

Thus it is shown how the present value of an annuity dependent upon the joint continuance of these three lives might be calculated, that being the sum of the present values thus determined, of the rents for all the years which, according to the table of mortality, the eldest life can survive.

39. But it is easy to see that the same method of reasoning may be used in the case of four, five, or six lives, and so on without limit. Whence this inference is obvious.

The present value of L.1 to be received at the expiration of a given term, provided that any given number of lives all survive it, may be found by multiplying the present value of L.1 to be received certainly at the end of the term, by the continual product of the numbers in the table of mortality against the ages greater respectively by the number of years in the term than the ages of the lives proposed, and dividing the last result of these operations by the continual product of the numbers in the table of mortality against the present ages of the proposed lives.

And by a series of similar operations, the present value of an annuity on the joint continuance of all these lives might be determined.

But it should be observed, that, in calculating the value of a life-annuity in this way, the denominator of the fractions expressing the values of the several years' rents, that is, the divisor used in each of the operations, remains always the same: the division should, therefore, be left till the sum of the numerators is determined; and one operation of that kind will suffice.

40. Enough has been said to show that these methods of constructing tables of the values of annuities on lives are practicable, though excessively laborious; and, in fact, all the early tables of this kind were constructed in that manner. We proceed now to show how such tables may be calculated with much greater facility.

Popular View.

41. By the method of No. 34, it will be found that, reckoning interest at 5 *per cent.*, the present value of L.1 to be received at the expiration of a year, provided that a life, now 89 years of age, survived till then, is $\frac{142 \times 0{\cdot}95238}{181}$. But the age of that life will then be 90 years, and the proprietor of an annuity of L.1 now depending upon it will, in that event, receive his annual payment of L.1 then due; therefore, if the value then of all the subsequent payments, that is, the value of an annuity on a life of 90, be 2·339 years' purchase, the present value of what the title to this annuity may produce to the proprietor at the end of the year will be the same as that of L.3·339, to be received then, if the life be still subsisting, or $\frac{142 \times 0{\cdot}952381}{181} \times \text{L.}3{\cdot}339 = \text{L.}2{\cdot}495$; which, therefore, will be the present value of an annuity of L.1 on a life of 89 years of age. That is to say, an annuity on that life will now be worth 2·495 years' purchase. (7.)

42. In the same manner it appears generally, that if unit be added to the number of years' purchase that an annuity on any life is worth, and the sum be multiplied by the present value of L.1 to be received at the end of a year, provided that a life one year younger survive till then, the product will be the number of years' purchase an annuity on that younger life is worth in present money.

43. But, according to the table of mortality, an annuity on the eldest life in it is worth nothing; therefore, the present value of L.1 to be received at the end of a year provided that the eldest life but one in the table survive till then, is the total present value of an annuity of L.1 on that life; which being obtained, the value of an annuity on a life one year younger than it may be found by the preceding number; and so on for every younger life successively.

EXEMPLIFICATION.

Rate of Interest 5 *per cent.*

Age of Life.	Value of an Annuity on that Life, increased by Unit,	Which being multiplied by 0·952381, and the Product by	Produces the value of an Annuity on the next younger Life,	Its Age being
104	1·000	$\frac{1}{3}$	0·317	103
103	1·317	$\frac{3}{5}$	0·753	102
102	1·753	$\frac{5}{7}$	1·192	101
101	2·192	$\frac{7}{9}$	1·624	100
100	2·624	$\frac{9}{11}$	2·045	99
99	3·045	$\frac{11}{14}$	2·278	98
98	3·278	$\frac{14}{18}$	2·428	97
97	3·428	$\frac{18}{23}$	2·555	96
96	3·555	$\frac{23}{30}$	2·596	95
95	3·596	$\frac{30}{40}$	2·569	94

44. Proceeding as in No. 36, it will be found that, at 5 *per cent.* interest, and according to the Carlisle table of mortality, the present value of L.1 to be received at the expiration of a year provided that a person now 89 years of age, and another now 99, be then living, is $\frac{142 \times 9 \times \text{L.}0{\cdot}952381}{181 \times 11}$; therefore, if the present value o an annuity of L.1 on the joint continuance of two lives, now aged 90 and 100 years respectively, be L.0·950, by reasoning as in No. 41, it will be found that the present value of an annuity on the joint continuance of two lives,

Popular View.

of the respective ages of 89 and 99 years, will be worth $\frac{142 \times 9 \times 0{\cdot}952381}{181 \times 11} \times 1{\cdot}950 = 1{\cdot}192$ years' purchase.

45. In this manner, commencing with the two oldest lives in the table that differ in age by ten years, and proceeding according to No. 43, the values of annuities on all the other combinations of two lives of the same difference of age may be determined.

The method is exemplified in the following specimen.

Ages of two Lives.	Value of an Annuity on their joint continuance, increased by Unit,	Which being multiplied by 0·952381, and the Product by	Produces the value of an Annuity on the two joint Lives one year younger respectively,	Their Ages being
94 & 104	1·000	$\frac{1 \times 40}{3 \times 54}$	0·235	93 & 103
93 & 103	1·235	$\frac{3 \times 54}{5 \times 75}$	0·508	92 & 102

90 & 100	1·950	$\frac{9 \times 142}{11 \times 181}$	1·192	89 & 99
89 & 99	2·192	$\frac{11 \times 181}{14 \times 232}$	1·280	88 & 98

46. Hence, and by what has been advanced in the 39th number of this article, it is sufficiently evident how a table may be computed of the values of annuities on the joint continuance of the lives in every combination of three, or any greater number; the differences between the ages of the lives in each combination remaining always the same in the same series of operations, while the calculation proceeds back from the combination in which the oldest life is the oldest in the table, to that in which the youngest is a child just born.

47. But when there are more than two lives in each combination, the calculations are so very laborious, on account principally of the great number of combinations, that no tables of that kind have yet been published, except three or four for three lives.

And in the books that contain tables of the values of two joint lives, methods are given of approximating towards the values of such combinations of two and of three lives as have not yet been calculated.

Therefore, assuming the values of annuities on single lives, and on the joint continuance of two or of three lives, to be given, we have next to show how the most useful problems respecting the values of any interests that depend upon the continuance or the failure of life may be resolved by them.

48. *Proposition* 1. The value of an annuity on the survivor of two lives, *A* and *B*, is equal to the excess of the sum of the values of annuities on the two single lives above the value of an annuity on their joint continuance.

49. *Demonstration.* If annuities on each of the two lives were granted to *P*, during their joint continuance he would have two annuities; but if *P* were only to receive these upon condition that, during the joint lives of *A* and *B*, he should pay one annuity to *Q*, then there would only remain one to be enjoyed by him or his heirs or assigns, until the lives both of *A* and *B* were extinct; whence the truth of the proposition is manifest.

50. *Prop.* 2. The value of an annuity on the joint continuance of the two last survivors out of three lives, *A*, *B*, and *C*, is equal to the excess of the sum of the values of annuities on the three combinations of two lives (*A* with *B*, *A* with *C*, and *B* with *C*) that can be formed out of them, above twice the value of an annuity on the joint continuance of all the three lives.

Popular View.

51. *Dem.* If one annuity were granted to *P* on the joint continuance of the two lives *A* and *B*, another on the joint continuance of *A* and *C*, and a third on the joint continuance of *B* and *C*; during the joint continuance of all the lives he would have three annuities.

But if he were only to receive these upon condition that he should pay two annuities to *Q* during the joint continuance of all the three lives, then there would only remain to himself one annuity during the joint existence of the last two survivors out of the three lives. And the truth of the proposition is manifest.

52. *Prop.* 3. The value of an annuity on the last survivor of three lives, *A*, *B*, and *C*, is equal to the excess of the sum of the values of annuities on each of the three single lives, together with the value of an annuity on the joint continuance of all the three, above the sum of the values of three other annuities; the first dependent upon the joint continuance of *A* and *B*, the second on that of *A* and *C*, and the third on *B* and *C*.

53. *Dem.* If annuities on each of the three single lives were granted to *R*, during the joint continuance of all the three he would have three annuities; and from the time of the extinction of the first life that failed, till the extinction of the second, he would have two.

So that he would have two annuities during the joint existence of the two last survivors out of the three lives; and besides these, a third annuity during the joint continuance of all the three.

Therefore, if out of these *R* were to pay one annuity to *P* during the joint continuance of the last two survivors out of the three lives, and another to *Q* during the joint continuance of all the three, he would only have left one annuity, which would be receivable during the life of the last survivor of the three.

But in the demonstration of the last proposition (51) it was shown, that the value of what he paid to *P* would fall short of the sum of the values of annuities dependent respectively on the joint continuance of *A* and *B*, of *A* and *C*, and of *B* and *C*, by two annuities on the joint continuance of all the three lives. Whence it is evident that the value of the annuities he paid both to *P* and *Q* would fall short of the sum of these three values of joint lives, only by the value of one annuity on the joint continuance of all the three lives.

Wherefore, if from the sum of the values of all the three single lives, the sum of the values of the three combinations of two that can be formed out of them were taken, there would remain less than the value of an annuity on the last survivor, by that of an annuity on the joint continuance of the three lives.

But if, to the sum of the values of the three single lives *A*, *B*, and *C*, there be added that of an annuity on the joint continuance of the three, and from the sum of these four values the sum of the values of the three combinations *A* with *B*, *A* with *C*, and *B* with *C* be subtracted, then the remainder will be the value of an annuity on the last survivor of the three lives; which was to be demonstrated.

54. *Prop.* 4. *Problem.* The law of mortality and the values of single lives at all ages being given, to determine the present value of an annuity on any proposed life, deferred for any assigned term.

55. *Solution.* Find the present value of an annuity on

Popular View

a life older than the proposed, by the number of years during which the other annuity is deferred; multiply this by the present value of L.1 to be received upon the proposed life surviving the term, and the product will be the value sought.

56. *Dem.* Upon the proposed life surviving the term, the annuity dependent upon it will be worth the same sum that an annuity on a life so much older is now worth; therefore it is evident that the deferred annuity is of the same present value as that sum to be received at the expiration of the term, provided the life survive it.

57. *Corollary.* In the same manner it appears, that the present value of an annuity on the joint continuance of any number of lives, deferred for a given term, may be found by multiplying the present value of an annuity on the joint continuance of the same number of lives, older respectively than the proposed by the number of years in the term, by the present value of L.1 to be received upon the proposed lives all surviving it.

58. A *temporary annuity* on any single life, or on the joint continuance of any number of lives, that is, an annuity which is to be paid during a certain term, provided that the single life or the other lives jointly subsist so long, together with an annuity on the same life or lives *deferred* for the same term, is evidently equivalent to an annuity on the whole duration of the same life or lives.

So that the value of an annuity on any life, or on the joint continuance of any number of lives, for an assigned term, is equal to the excess of the value of an annuity on their whole duration, with immediate possession, above the value of an annuity on them deferred for the term.

59. Whatever has been advanced from No. 48 to 53 inclusive, respecting the values of annuities for the whole duration of the lives whereon they depend, will apply equally to those which are either deferred or temporary; and therefore, to determine the value of any deferred or temporary annuity dependent upon the last survivor of two or of three lives, or upon the joint continuance of the last two survivors out of three lives, we have only to substitute temporary or deferred annuities, as the case may require, for annuities on the whole duration of the lives; and the result will accordingly be the value of a temporary or deferred annuity on the life of the last survivor, or on the joint lives of the two last survivors.

60. *Prop.* 5. *A* and *B* being any two proposed lives now in existence, the present value of an annuity to be payable only while *A* survives *B*, is equal to the excess of the value of an annuity on the life of *A* above that of an annuity on the joint existence of both the lives.

61. *Dem.* If an annuity on the life of *A*, and to be entered upon immediately, were now granted to *P* upon condition that he should pay it to *B* during the joint lives of *A* and *B*, it is evident that there would only remain to *P* an annuity on the life of *A* after the decease of *B*; whence the truth of the proposition is manifest.

62. When any thing is affirmed or demonstrated of *any life or lives*, it is to be understood as applying equally to any proposed single life, or to the joint continuance of the whole of any number of lives that may be proposed together, or to that of any assigned number of the last survivors of them, or to the last surviving life of the whole.

63. *Prop.* 6. The present value of the reversion of a perpetual annuity after the failure of any life or lives, is equal to the excess of the present value of the perpetuity, with immediate possession, above the present value of an annuity on the same life or lives.

64. *Dem.* If a perpetual annuity with immediate possession were granted to *P*, upon condition that he should pay the annual produce to another individual during the existence of the life or lives proposed, it is evident that there would only remain to *P* the reversion after the failure of such life or lives; and the present value of that reversion would manifestly be as stated above.

Popular View.

65. The 6th, 7th, and 8th tables at the end of this article, which have been extracted from the 19th, 21st, and 22d respectively, in Mr Milne's *Treatise on Annuities*, will serve to illustrate the application of these propositions to the solution of questions in numbers.

In all the following examples, we suppose the lives to be such as the general average of those from which the Carlisle table of mortality was constructed, and the rate of interest to be 5 *per cent.*

66. *Ex.* 1. What is the present value of an annuity on the joint lives, and the life of the survivor of two persons now aged 40 and 50 years respectively?

According to No. 48, the process is as follows:

Value of a single life of	40	13·390	(by Table VI.)
	50	11·660	
	sum	25·050	
Subtract the value of their joint lives,		9·984	(Table VIII.)
	remains	15·066	years' purchase, the required value.

And if the annuity be L.200, its present value will be L.3013·2, or L.3013. 4s.

67. *Ex.* 2. The lives *A*, *B*, and *C*, being now aged 50, 55, and 60 years respectively, an annuity on the joint continuance of all the three is worth 6·289 years' purchase, what is the value of an annuity on the joint existence of the last two survivors of them?

According to No. 50, the process is thus:

Ages.	Values.	
50 & 55	8·528	(Table VII.)
55 & 60	7·106	
50 & 60	7·601	(Table VIII.)
sum	23·235	
Subtract 2 × 6·289 =	12·578	
remains	10·657	years' purchase, the required value.

Therefore, if the annuity were L.300, it would be worth L.3197. 2s. in present money.

68. *Ex.* 3. Required the value of an annuity on the last survivor of the three lives in the last example.

Proceeding according to No. 52, we have

Ages.	Values.	
50	11·660	(Table VI.)
55	10·347	
60	8·940	
50, 55, & 60	6·289	(No. 67).
sum	37·236	
Subtract the sum of the values of annuities on the three combinations of two lives,	23·235	(No. 67.)
remains	14·001	years' purchase,

the required value. And if the annuity were L.300, it would now be worth L.4200. 6s.

69. *Ex.* 4. What is the present value of an annuity on a life now 45 years of age, which is not to be entered upon until the expiration of ten years; the first payment thereof being to be made at the expiration of eleven years from this time, if the life survive till then?

Popular View.

Solution.

The present value of an annuity on a life of 55 is 10·347 (Table VI.), and the present value of L.1 to be received upon the proposed life attaining to the age of 55, is $\frac{4073}{4727} \times 0{\cdot}613913$; therefore, by No. 55, the required value is $\frac{4073 \times 0{\cdot}613913 \times 10{\cdot}347}{4727} = 5{\cdot}473$ years' purchase; so that if the annuity were L.200, its present value would be L.1094. 12s.

70. *Ex.* 5. Required the present value of an annuity to be received for the next ten years, provided that a person now 45 years of age shall so long live.

Solution.

The present value of an annuity on a life of 45, to be entered upon immediately, is 12·648 (Table VI.)
Subtract that of an annuity on the same life deferred 10 years, } 5·473 (69.)

the remainder 7·175

is the required number of years' purchase. And if the annuity were L.200, its present value would be L.1435.

71. *Ex.* 6. An annuity on a life of 45, deferred 10 years, was shown in No. 69 to be worth 5·473 years' purchase in present money; let it be required to determine the equivalent annual payment for the same, to be made at the end of each of the next 10 years, but subject to failure upon the life failing in the term.

Solution.

The present value of L.1 *per annum* on the proposed life for the next 10 years has just been shown to be L.7·175, and this, multiplied by the required annual payment, must produce L.5·473; that payment must, therefore, be $\frac{5{\cdot}473}{7{\cdot}175} = 0{\cdot}76279$. And since the annual payment for the deferred annuity of L.1 *per annum* would be L.0·76279, that for an annuity of L.200 must be L.152. 11s. 2d.

72. *Ex.* 7. Let the present value be required of an annuity on a life now 40 years of age, to be payable only while that life survives another now of the age of 50 years.

From the present value of a life of 40, } 13·390 (Table VI.)
Subtract that of the two joint lives, } 9·984 (Table VIII.)

the remainder, 3·406

years' purchase, is the required value. (60.)

Therefore, if the annuity were L.100, it would be worth L.340. 12s. in present money.

73. If the annuity in the last example were to be paid for by a constant annual premium at the end of each year while both the lives survived; by reasoning as in No. 71, it will be found, that such annual premium for an annuity of L.1 should be $\frac{3{\cdot}406}{9{\cdot}984} =$ L.0·341146; for an annuity of L.100 it should therefore be L.34. 2s. 3½d.

74. But if one of the equal premiums for this annuity is to be paid down now, and another at the end of each year while both the lives survive, the number of years' purchase the whole of these premiums are worth will evidently be increased by unit; on account of the payment made now, it will therefore be 10·984; and each premium for an annuity of L.1 must, in this case, be $\frac{3{\cdot}406}{10{\cdot}984} =$ L.0·310087; for an annuity of L.100 it should therefore be L.31. 0s. 2d.

75. *Ex.* 8. Let it be required to determine the present value of the reversion of a perpetual annuity after the failure of a life now 50 years of age.

Solution.

The value of the perpetuity is 20 years' purchase. (8.)
Subtract that of an annuity on the life of 50, } 11·660 (Table VI.)

remains 8·34 years' purchase,

the required value of the reversion. (63.)

So that if the annuity were L.300, its present value would be L.2502.

76. In the same manner it will be found, by the 68th number and those referred to in the last example, that the reversion of a perpetuity, after the failure of the last survivor of three lives, now aged 50, 55, and 60 years respectively, is worth 5·999 years' purchase in present money; therefore, if it were L.100 *per annum*, its present value would be L.599. 18s.

III.—Of Assurances on Lives.

77. An assurance upon a life or lives is a contract by which the office or underwriter, in consideration of a stipulated premium, engages to pay a certain sum upon such life or lives failing within the term for which the assurance is effected.

78. If the term of the assurance be the whole duration of the life or lives assured, the sum must necessarily be paid whenever the failure happens; and, in what follows, that payment is always supposed to be made at the end of the year in which the event assured against takes place; the anniversary of the assurance, or the day of the date of the policy, being accounted the beginning of each year.

79. At the end of the year in which any proposed life or lives may fail, the proprietor of the reversion of a perpetual annuity of L.1 after their failure will receive the pound then due, and will at the same time enter upon the perpetuity; therefore, the present value of the reversion is the same as that of L.1 added to the money a perpetual annuity of L.1 would cost, supposing this sum not to be receivable until the expiration of the year in which the failure of the life or lives might happen.

80. Hence we have this proportion. As the value of a perpetuity increased by unit is to L.1, so is the present value of the reversion of a perpetual annuity of L.1, after the failure of any life or lives, to the present value of L.1, receivable at the end of the year in which such failure shall take place.

81. Therefore, *if the value of an annuity of one pound on any life or lives be subtracted from that of the perpetuity, and the remainder be divided by the value of the perpetuity increased by unit, the quotient will be the value, in present money, of the assurance of one pound on the same life or lives.* (63.)

82. *Ex.* 1. What is the present value of L.1 to be received at the end of the year in which a life now 50 years of age may fail?

The rate of interest being 5 *per cent.*, the value of the perpetuity is 20 years' purchase, and that of the life 11·66; the answer therefore is $\frac{20-11{\cdot}66}{20+1} = \frac{8{\cdot}34}{21} =$ L.0·397143. And if the sum assured were L.1000, the present value of the assurance would be L.397. 2s. 10d.

83. When the term of a life-assurance exceeds one year, its whole value is hardly ever paid down at the time that the contract is entered into; but in the instrument (called a policy) whereby the assurance is effected, an equivalent annual premium is stipulated for, payable at the *commence-*

Popular View.

ment of each year during the term, but subject to failure with the life or lives assured.

84. But by reasoning as in No. 74, it will be found that an annual premium, payable at the *commencement* of each year in the whole duration of the life or lives assured, will be worth one year's purchase more than an annuity on them payable at the *end* of each year; and, consequently, that if the value in present money of an assurance on any life or lives be divided by the number of years' purchase an annuity on the same life or lives is worth, increased by unit, the quotient will be the equivalent annual premium for the same assurance.

85. *Ex.* 2. Required the annual premium for the assurance of L.1 on a life of 50 years of age.

In No. 82 the single premium for that assurance was shown to be 0·397143, and the value of an annuity on the life is 11·66; therefore, by the preceding number, the required annual premium will be $\frac{0 \cdot 397143}{12 \cdot 66} = \cdot 0313699$ for the assurance of L.1; and for the assurance of L.1000 it will be L.31. 7s. 5d.

86. *Ex.* 3. Let both the single payment in present money, and the equivalent annual premium, be required for the assurance of L.1, on the joint continuance of two lives of the respective ages of 45 and 50 years.

The value of an annuity of L.1 on the joint continuance of these two lives appears by Table VII. to be L.9·737, therefore $\frac{20-9 \cdot 737}{20+1} = \frac{10 \cdot 263}{21} =$ L.0·488714 is the single premium, and $\frac{0 \cdot 488714}{10 \cdot 737} =$ L.0·0455168 the equivalent annual one, for the assurance of L.1 to be paid at the end of the year in which that life becomes extinct which may happen to fail the first of the two.

Therefore, if the sum assured were L.500, the total present value of the assurance would be L.244. 7s. 2d., and the equivalent annual premium L.22. 15s. 2d.

87. *Ex.* 4. Let both the single and the equivalent annual premium be required for the assurance of L.1 on the life of the survivor of two persons now aged 40 and 50 years respectively.

The value of an annuity on the survivor of these two lives was shown in No. 66 to be 15·066, therefore, by No. 81, the single premium will be $\frac{20-15 \cdot 066}{20+1} = \frac{4 \cdot 934}{21}$ = L.0·234952; and, by No. 84, the annual one will be $\frac{\text{L.}0 \cdot 234952}{16 \cdot 066} =$ L.0·0146242.

That is, for the assurance of L.1 to be received at the end of the year in which the last surviving life of the two becomes extinct.

Therefore, for the assurance of L.5000, the single premium will be L.1174. 15s. 2d., the equivalent annual one L.73. 2s. 5d.

88. *Ex.* 5. What should the single and equivalent annual premiums be for an assurance on the last survivor of three lives of the respective ages of 50, 55, and 60 years?

The value of an annuity on the last survivor of them was shown in No. 68 to be 14·001, the single premium should therefore be $\frac{20-14 \cdot 001}{20+1} = \frac{5 \cdot 999}{21} =$ L.0·285666, and the annual $\frac{\text{L.}0 \cdot 285666}{15 \cdot 001} =$ L.0·0190431, for the assurance of L.1 to be received at the end of the year in which the last surviving life of the three may fail.

For the assurance of L.2000, the single premium would therefore be L.571. 6s. 8d., the annual one L.38. 1s. 9d.

Popular View.

89. *Lemma.* If an annuity be payable at the *commencement* of each year which some assigned life or lives may *enter upon* in a given term, the number of years' purchase in its present value will exceed by unit the number of years' purchase in the present value of an annuity on the same life or lives for one year less than the given term, but payable, as annuities generally are, at the *end* of each year.

Demonstration. Since the proposed life or lives can only enter upon any year after the first by surviving the year that precedes it, the receipt of each of the payments after the first, that are to be made at the commencement of the year, will take place at the same time and upon the same conditions as that of the rent for the year then expired of the life-annuity, for a term one year less than the term proposed: this last-mentioned annuity will therefore be worth, in present money, just the same number of years' purchase as all the payments subsequent to the first which may be made at the commencements of the several years.

And since the first of these is to be made immediately, the present value of the whole of them will evidently exceed the number of years' purchase last mentioned by unit; which was to be demonstrated.

90. If, while the rest remains the same, the payment of the annuity which depends upon the assigned life or lives *entering upon* any year is not to be made until the end of that year; as the condition upon which every payment is to be made will remain the same, but each of them will be one year later; the only alteration in the value of the whole will arise from this increase in the remoteness of payment, by which it will be reduced in the ratio of L.1 to the present value of L.1 receivable at the end of a year. (2.)

91. When the value of an annuity on any proposed life or lives for an assigned term is given, it is evident that the value of an annuity on the same life or lives for one year less may be found, by subtracting from the given value the present value of the rent to be received upon the proposed life or lives surviving the term assigned.

92. *Proposition.* The present value of an assurance on any proposed life or lives for a given term is equal to the excess of the value of an annuity to be paid at the end of each year which the life or lives proposed may *enter upon* in the term, above the value of an annuity on them for the same term, but dependent, as usual, upon their surviving each year.

Demonstration. If an annuity, payable at the end of each year which the proposed life or lives may enter upon during the given term, be granted to P upon condition that he shall pay over what he receives to Q at the end of each year which the same life or lives may survive, it is manifest that there will only remain to P the rent for the year in which the proposed life or lives may fail; that is, the assurance of that sum thereon for the given term (77); which was to be demonstrated.

93. From the last four numbers (89–92) we derive the following

Rule

for determining the present value of an assurance on any life or lives for a given term.

Add unit to the value of an annuity on the proposed life or lives for the given term, and from the sum subtract the present value of one pound to be received upon the same life or lives surviving the term; multiply the remainder by the present value of L.1 *to be received certainly at the end of a year, and from the product subtract the present value of an annuity on the proposed life or lives for the term.*

This last remainder will be the value in present money

of the assurance of L.1 during the same term on the life or lives proposed.

94. It has been shown above (34–39) how the present value of L.1 receivable upon any single or joint lives surviving an assigned term may be found. And all that was demonstrated from No. 48 to 53 inclusive, respecting annuities on the last survivor of two or of three lives, or on the joint continuance of the two last survivors out of three lives, is equally true of any particular year's rent of those annuities. Hence it is evident how the present value of L.1, to be received upon the last survivor of two or of three lives, or upon the last two survivors out of three lives, surviving any assigned term, may be found.

95. *Example.* Required the present value of L.1, to be received at the end of the year in which a life now forty-five years of age may fail, provided that such failure happen before the expiration of ten years.

Here the present value of L.1, to be received on the life surviving the term, will be found to be L.0·528976, and the value of an annuity on the proposed life for the term is 7·175. (70.)

From	8·175
subtract	0·528976
the remainder	7·646024
being multiplied by	0·952381
produces	7·28193
from this subtract	7·17500

remains L.0·10693, the required value of the assurance; and if the sum assured were L.3000, the value of the assurance in present money would be L.320. 15s. 7d.

96. By numbers 89, 91, and 95, it appears that an annuity, payable at the commencement of each of the next ten years that a life of 45 enters upon, is worth 7·646 years' purchase; therefore, $\frac{0\cdot10693}{7\cdot646} =$ L.0·013985 will be the annual premium for the assurance of L.1 for ten years on that life. For the assurance of L.3000, it will therefore be L.41. 19s. 1d.

97. When the term of the assurance is the whole duration of the life or lives assured, L.1 to be received upon their surviving the term is worth nothing; and an annuity on the lives for the term is also for their whole duration.

Therefore from No. 93 we derive the following

Rule

for determining the present value of an assurance on any life or lives.

Add unit to the value of an annuity on the proposed life or lives; multiply the sum by the present value of L.1 *to be received certainly at the end of a year, and from the product subtract the value of an annuity on the same life or lives.*

The remainder will be the value of the assurance in present money.

98. *Example.* Required the present value of L.1 to be received at the end of the year in which the survivor of two lives may fail, their ages now being 40 and 50 years respectively.

The value of an annuity on these lives was shown in No. 66 to be 15·066.

Multiply 16·066 by 0·952381, from the product 15·3009 subtract 15·066, the remainder L.0·2349 is the required value, agreeably to No. 87.

And, in all other cases, the values determined by the rule in the preceding number will be found to agree with those obtained by the method of No. 81.

99. When an assurance on any life or lives has been effected at a constant annual premium, and kept up for some time by the regular payment of that premium, the annual premium required for a new assurance of the same sum on the same life or lives will, on account of the increase of age, be greater than that at which the first assurance was effected: Therefore the present value of all these greater annual premiums, that is, the total present value of the new assurance, will exceed the present value of all the premiums that may hereafter be received under the existing policy. And the excess will evidently be the value of the policy, supposing the life or lives to be still insurable; that being the only advantage which can now be derived from the premiums already paid.

So that if the present value of all the future annual premiums to be paid under an existing policy, for the assurance of a certain sum upon any life or lives, be subtracted from the present value of the assurance of the same sum on the same life or lives, the remainder will be the value of the policy.

100. *Example.* L.1000 has been assured some years on a life now 50 years of age, for its whole duration, at the annual premium of L.20, one of which has just now been paid. What is the value of the policy?

The present value of the assurance of L.1000 on that life has been shown in No. 82 to be L.397. 2s. 10d.; and an annuity on the life being worth 11·66 years' purchase (Table VI.), the present value of all the premiums to be paid in future under the existing policy is 11·66 × L.20 = L.233. 4s.; the value of the policy. therefore, is L.163. 18s. 10d.

Immediately before the payment of the premium the value of the policy would evidently have been less by the premium then due.

101. In our investigations of the values of annuities on lives, we have hitherto assumed that no part of the rent is to be received for the year in which the life wherewith the annuity may terminate fails.

But if a part of the annuity is to be received at the end of that year, proportional to the part of the year which may have elapsed at the time of such failure; as, in a great number of such cases, some of the lives wherewith the annuity terminates will fail in every part of the year, and as many, or very nearly so, in any one part of it as in any other: we may assume that, upon an average, half a year's rent will be received at the end of the year in which such failure happens; and therefore, that by the title to what may be received after the failure of the life or lives whereon the annuity depends, the present value of that annuity will be increased by the present value of the assurance of half a year's rent on the same life or lives.

102. Thus, for example, the present value of the assurance of L.1 on a life of 50 years of age having in No. 82 been shown to be L.0·397143, the value of an annuity of L.1 on that life, when payable till the last moment of its existence, will exceed L.11·66, its value if only payable until the expiration of the last year it survives, by $\left(\frac{\text{L.}0\cdot397143}{2} =\right)$ L.0·199; it will therefore be L.11·859.

103. If at the end of the year in which an assigned life *A* may fail, *Q* or his heirs are to receive L.1, and are at the same time to enter upon an annuity of L.1, to be enjoyed during another life *P*, to be then fixed upon; the present value of *Q's* interest will evidently be the same as that of the assurance on the life of *A*, of a number of pounds, exceeding by unit the number of years' purchase in the value of an annuity on the life of *P*, at the time of nomination.

104. What is the present value of the next presentation to a living of the clear annual value of L.500, *A*, the present incumbent, being now 50 years of age; supposing

Popular View.

the age of the clerk presented to be 25 at the end of the year in which the present incumbent dies; also, that he takes the whole produce of the living for that year?

By Table VI. it will be found that the value of an annuity of L.1 on a life of 25 is L.15·303; and in No. 82 it has been shown, that the present value of the assurance of L.1 on a life of 50 is L.0·397143. Hence, and by the last number, it appears that if the annual produce of the living were but L.1, the present value of the next presentation would be L.16·303 × 0·397143 = L.6·47467. The required value, therefore, is L.3237. 6s. 9d.

105. If to the value of the succeeding life, determined according to No. 103, the value of the present be added, the sum of these will evidently be the present value of both the lives in succession; and, in the case of the preceding number, will be 6·475 + 11·66 = 18·135 years' purchase.

106. In No. 103 we proceeded upon the supposition that the annuity on the present life is only payable up to the expiration of the last year it survives, and, consequently, that the succeeding life takes the whole rent for the year in which the present fails.

But if the succeeding life is only to take a part of that rent, in the same proportion to the whole as the portion of the year which intervenes between the failure of the present life and the end of the year is to the whole year, then, by reasoning as in No. 101, it will be found that the portion of that rent which the succeeding life will receive may be properly assumed to be one half. And, instead of increasing the number of years' purchase the annuity on the succeeding life will be worth at the end of the year in which the other fails by unit, we must only add one half to that number, in order that the present value of the assurance of the sum on the existing life may be the number of years' purchase which all that may be received during the succeeding life is now worth.

107. The value of the succeeding life, in the case of No. 104, will, upon this hypothesis, be 15·803 × 0·397143 = 6·27605 years' purchase.

And this appears to be the most correct way of calculating the value of an annuity on a succeeding life, although that of No. 103 proceeds upon the principle on which life-interests are generally valued.

108. But the value of two lives in succession will be the same on both hypotheses; the rent for the year in which the first may fail being, in the one case, given entirely to the successor; and, in the other, divided equally between the two.

This is also true of any greater number of successive lives.

PART II.

109. We now proceed to treat the subject of annuities *Algebraically*.

I.—On Annuities-Certain.

Let r denote the *simple interest* of L.1 for one year.
s, any *sum* put out at interest.
n, the *number of years* for which it is lent.
m, its *amount* in that time.
a, an *annuity* for the same time. (3 and 4.)
M, the *amount* to which that *annuity* will increase when each payment is laid up as it becomes due, and improved at compound interest until the end of the term.
V, the *present value* of the same annuity. (6.)

110. Then, reasoning as in the first number of this article, it will be found that $m = s\,(1+r)^n$. And by No. 2 it appears that the present value of s pounds to be received certainly at the expiration of n years, is $s\frac{1}{(1+r)^n}$, or $s\,(1+r)^{-n}$.

111. The amount of L.1 in n years being $(1+r)^n$, its increase in that time will be $(1+r)^n - 1$; and when it is considered that this increase arises entirely from the simple interest (r) of L.1 being laid up at the end of each year, and improved at compound interest during the remainder of the term, it must be obvious that $(1+r)^n - 1$ is the amount of an annuity of r pounds in that time; but $r : a :: (1+r)^n - 1 : \frac{a}{r}\left[(1+r)^n - 1,\right]$ which, therefore, is equal to M, the amount of an annuity of a pounds in n years.

112. Reasoning as in No. 8, it will be found, that since $r : 1 :: a : \frac{a}{r}$, the present value of a perpetual annuity of a pounds is $\frac{a}{r}$.

113. If two persons, A and B, purchase a perpetuity of a pounds between them, which A and his heirs or assigns are to enjoy during the first n years, and B and his heirs or assigns for ever after. Since the value of the perpetuity to be entered upon immediately has just been shown to be $\frac{a}{r}$, the present value of B's share, that is, the present value of the same perpetuity when the entrance thereon is deferred until the expiration n years, will be $\frac{a}{r}(r+1)^{-n}$, (110); and the value of the share of A will be thus much less than that of the whole perpetuity (21), therefore equal to $\frac{a}{r}\left[1 - (1+r)^{-n}\right] = $ V, the present value of an annuity of a pounds for the term of n years certain.

114. If the annuity is not to be entered upon until the expiration of d years, but is then to continue n years, its value at the time of entering upon it will be $\frac{r}{a}\left[1 - (1+r)^{-n}\right]$, as has just been shown; therefore its present value will be

$$\frac{a}{r}\left[(1+r)^{-d} - (1+r)^{-(d+n)}\right] = \text{V}. \quad (110.)$$

115. In the same manner it appears that, when the entrance on a perpetuity of a pounds is deferred d years, its present value will be $\frac{a}{r}(1+r)^{-d}$. (110 and 112.)

116. q being any number whatever, whole, fractional, or mixed, let λq denote its logarithm, and $\varkappa q$ the arithmetical complement of that logarithm; so that these equations may obtain, $\lambda\frac{1}{q} = -\lambda q = \varkappa q$. Then, for the resolution of the principal questions of this kind by logarithms, we shall have these formulæ.

1. *Amount of a sum improved at interest.*

$$\lambda m = n\lambda(1+r) + \lambda s. \quad (110.)$$

2. *Amount of an annuity when each payment is laid up as it becomes due, and improved at interest until the expiration of the term.*

Algebraical View.

$$\lambda M = \lambda\left[(1+r)^n - 1\right] + \lambda a + xr. \quad (111.)$$

3. *Value of a lease or an annuity.*

$$\lambda V = \lambda\left[1 - (1+r)^{-n}\right] + \lambda a + xr. \quad (113.)$$

4. *Value of a deferred annuity, or the renewal of any number of years lapsed in the term of a lease.*

$$\lambda V = \lambda\left[(1+r)^{-d} - (1+r)^{-(d+n)}\right] + \lambda a + xr. \quad (114.)$$

5. *Value of a deferred perpetuity, or the reversion of an estate in fee-simple, after an assigned term.*

$$\lambda V = \lambda a + xr + dx(1+r). \quad (115.)$$

By means of each of these equations, it is manifest that any one of the quantities involved in it may be found when the rest are given.

117. If the interest be convertible into principal ν times in the year, at ν equal intervals; since the interest of L.1 for one of these intervals will be $\frac{r}{\nu}$ (109), and the number of conversions of interest into principal in n years νn; to adapt the formula in No. 110 to this case, we have only to substitute $\frac{r}{\nu}$ for r, and νn for n, in the equation $m = s(1+r)^n$ there given, whereby it will be transformed to this, $m = s\left(1+\frac{r}{\nu}\right)^{\nu n}$.

118. According as ν is equal to 1, 2, 4, or is infinite, that is, according as the interest is convertible into principal yearly, half-yearly, quarterly, or continually, let m be equal to Y, H, Q, or C; so shall

$$\text{Y} = s(1+r)^n,$$

$$\text{H} = s\left(1+\frac{r}{2}\right)^{2n},$$

$$\text{Q} = s\left(1+\frac{r}{4}\right)^{4n},$$

$$\text{and C} = s \cdot \text{N};$$

N being the number of which nr is the hyperbolic logarithm, and $nr \times 0{\cdot}43429448$ its logarithm in Briggs' *System*, and the common tables.

119. From No. 117 and 110, it follows that the present value of s pounds to be received at the end of n years, when the interest is convertible into principal at ν equal intervals in each year, is $s\left(1+\frac{r}{\nu}\right)^{-\nu n}$.

120. When the present values and the amounts of annuities are desired, let the interest be convertible into principal at ν equal intervals in the year, while the annuity is payable at π intervals therein, the amount of each payment being $\frac{a}{\pi}$.

121. *Case* 1. μ being any whole number not greater than ν, let $\frac{1}{\pi} = \frac{\mu}{\nu}$, so that the interest may be convertible into principal μ times in each of the intervals between the payments of the annuity.

Then will the amount of L.1 at the expiration of the period $\frac{1}{\pi}$ be $\left(1+\frac{r}{\nu}\right)^{\mu}$ (117), and the interest of L.1 for the same time will be $\left(1+\frac{r}{\nu}\right)^{\mu} - 1$; whence the present value of the perpetuity will be $\dfrac{\frac{1}{\pi}a}{\left(1+\frac{r}{\nu}\right)^{\mu}-1}$ (8), and the value of the same deferred n years, will be $\frac{a}{\pi} \cdot \dfrac{\left(1+\frac{r}{\nu}\right)^{-\nu n}}{\left(1+\frac{r}{\nu}\right)^{\mu}-1}$ (119), therefore the present value of the annuity to be entered upon immediately, and to continue n years, will be

$$\frac{a}{\pi} \cdot \frac{1-\left(1+\frac{r}{\nu}\right)^{-\nu n}}{\left(1+\frac{r}{\nu}\right)^{\mu}-1} = \text{V}.$$

122. *Case* 2. μ being any whole number greater than π, let $\frac{1}{\nu} = \frac{\mu}{\pi}$, so that the annuity may be payable μ times in each of the intervals between the payments of interest, or the conversion thereof into principal.

Then, at the expiration of the $\frac{1}{\nu}$th of a year, when the interest on the purchase-money is first payable or controvertible, the interest on all the $\mu - 1$ payments of the annuity previously made will be

$$\frac{ar}{\pi\pi}\left[(\mu-1)+(\mu-2)+(\mu-3)+\ldots\ldots+3+2+1\right]$$

$= \frac{a}{\pi} \cdot \frac{r\mu(\mu-1)}{2\pi}$; to which adding the μ payments of $\frac{a}{\pi}$ each (including the one only then due), the sum $\frac{a}{\pi}\left[\mu + \frac{r\mu(\mu-1)}{2\pi}\right]$, is the simple interest which the value of the perpetuity should yield at the expiration of each νth part of a year, in order to supply the deficiency (both of principal and interest) that would be occasioned during each of those periods, in any fund out of which the several payments of the annuity might be taken, as they respectively became due; and since $\frac{r}{\nu} : \frac{a}{\pi}\left[\mu + \frac{r\mu(\mu-1)}{2\pi}\right]$ $:: 1 : \frac{a\nu}{r\pi}\left[\mu + \frac{r\mu(\mu-1)}{2\pi}\right] = a\left(\frac{1}{r} + \frac{\mu-1}{2\pi}\right)$, this last expression will be the value of such perpetuity with immediate possession (8); the value of the same deferred n years will therefore be $a\left(\frac{1}{r}+\frac{\mu-1}{2\pi}\right) \times \left(1+\frac{r}{\nu}\right)^{-\nu n}$ (119). Whence it appears that the present value of the annuity to be entered upon immediately, and to continue n years, will be $a\left(\frac{1}{r}+\frac{\mu-1}{2\pi}\right) \cdot \left[1-\left(1+\frac{r}{\nu}\right)^{-\nu n}\right] = \text{V}.$

123. *Case* 3. When, in consequence of the annuity being always payable at the same time that the interest is convertible, $\nu = \pi$.

Since the interest of L.1 at the expiration of the period $\frac{1}{\pi}$ will be $\frac{r}{\pi}$, the value of the perpetuity will be $\dfrac{\frac{1}{\pi}a}{\frac{1}{\pi}r} = \frac{a}{r}$ (8), whence, proceeding as before, we obtain the present value of the annuity, $\frac{a}{r}\left[1-\left(1+\frac{r}{\nu}\right)^{-\nu n}\right] = \text{V}.$ Whence $\nu = \pi$, and consequently $\mu = 1$, the values of V given in the two preceding cases, will be found to coincide with this.

124. According as ν and π are each equal to 1, 2, 4, or are infinite; that is, according as the interest and the annuity are each payable yearly, half-yearly, quarterly, or continually, let V be equal to y, h, q, or c, then will

$$y = \frac{a}{r}\left[1-(1+r)^{-n}\right],$$

Algebraical View.

$$h=\frac{a}{r}\left[1-\left(1+\frac{r}{2}\right)^{-2n}\right]$$

$$q=\frac{a}{r}\left[1-\left(1+\frac{r}{4}\right)^{-4n}\right],$$

and $c=\frac{a}{r}\left[1-\frac{1}{\text{N}}\right]$, N being as in No. 118.

125. The amount of an annuity is equal to the sum to which the purchase-money would amount if it were put out and improved at interest during the whole term.

For, from the time of the purchase of the annuity, whatever part of the money that was paid for it may be in the hands of the granter, he must improve thus to provide for the payments thereof; and if the purchaser also improve in the same manner all he receives, the original purchase-money must evidently receive the same improvement during the term, as if it had been laid up at interest at its commencement.

126. The periods of conversion of interest into principal, and of the payment of the annuity being still designated as in No. 120; since in n years the number of periods of conversion will be m, in the

1*st Case*, where the interest is convertible μ times in each of the intervals between the payments of the annuity, we have $\left(1+\frac{r}{\nu}\right)^{m}\text{V}=\frac{a}{\pi}\cdot\frac{\left(1+\frac{r}{\nu}\right)^{m}-1}{\left(1+\frac{r}{\nu}\right)^{\mu}-1}=\text{M}$. (117, 121, and 125.) In the 2*d Case*, when the annuity is payable μ times, in each interval between the conversions of interest,

$$\left(1+\frac{r}{\nu}\right)^{m}\text{V}=a\left[\frac{1}{r}+\frac{\mu-1}{2\pi}\right]\cdot\left[\left(1+\frac{r}{\nu}\right)^{m}-1\right]$$

$=\text{M}$. (117, 122, and 125.)

And, in the 3*d Case*, when the annuity is always payable at the same time that the interest is convertible, $\left(1+\frac{r}{\nu}\right)^{m}\text{V}=\frac{a}{r}\left[\left(1+\frac{r}{\nu}\right)^{m}-1\right]=\text{M}$.(117, 123, and 125.)

127. According as ν and π are each equal to 1, 2, 4, or are infinite; that is, according as the interest and the annuity are each payable yearly, half-yearly, quarterly, or continually, let M be denoted by y', h', q', or c';

then will
$$y'=\frac{a}{r}\left[(1+r)^{n}-1\right],$$

$$h'=\frac{a}{r}\left[\left(1+\frac{r}{2}\right)^{2n}-1\right],$$

$$q'=\frac{a}{r}\left[\left(1+\frac{r}{4}\right)^{4n}-1\right],$$

and $c=\frac{a}{r}(\text{N}-1)$; N being as in No. 118.

128. *Example* 1. What will L.320 amount to, when improved at compound interest during 40 years, the rate of interest being 4 *per cent. per annum?*

By the first formula in No. 116, the operation will be as follows:

$$\begin{aligned} 1\times r &= 1{\cdot}04\ \lambda\ 0{\cdot}01703334\\ &\qquad +n=40\\ (1+r)^{n}&\ \lambda\ 0{\cdot}6813336\\ s&=320\ \lambda\ 2{\cdot}5051500\\ m&=1536{\cdot}327\ \lambda\ 3.1864836 \end{aligned}$$

And the answer is L.1536. 6s. 6½d.

129. *Ex.* 2. If the interest were convertible into principal every half-year, the operation, according to No. 117, would be thus:

$$\begin{aligned} 1+\frac{r}{2}&=1{\cdot}02\ \lambda\ 0{\cdot}00860017\\ &\qquad\times m=80\\ &\qquad 0{\cdot}6880136\\ s&=320\ \lambda\ 2{\cdot}5051500\\ m&=1560{\cdot}14\ \lambda\ 3{\cdot}1931636 \end{aligned}$$

So that in this case the amount would be L.1560. 2s. 9½d.

130. *Ex.* 3. Required the present value of an annuity of L.250 for 30 years, reckoning interest at 5 *per cent.*

By the third formula in No. 116, the operation will be thus:

$$\begin{aligned} \lambda(1+r)^{-1}&=\varkappa\ 1{\cdot}05=\bar{1}{\cdot}9788107\\ &\qquad\times n=30\\ (1+r)^{-n}&=\cdot23137704\ \lambda\ \bar{1}{\cdot}3643210\\ 1-(1+r)^{-n}&=\cdot76862296\ \lambda\ \bar{1}{\cdot}8857133\\ a&=250\ \lambda\ 2{\cdot}3979400\\ r&=\cdot05\ \varkappa\ 1{\cdot}3010300\\ \text{V}&=3843{\cdot}114\ \lambda\ 3{\cdot}5846833 \end{aligned}$$

And the required value is L.3843. 2s. 3¼d.

131. *Ex.* 4. The rest being still the same, if the annuity in the last example be payable half-yearly, in the formula of No. 122 ν will be equal to 1, $\pi=2$, and $\mu=2$; that formula will therefore become $a\left(\frac{1}{r}+\frac{1}{4}\right)\cdot\left[1-(1+r)^{-n}\right]$ $=\text{V}$; and the operation will be thus:

$$\left.\begin{aligned} 1-(1+r)^{-n}&\ \lambda\ \bar{1}{\cdot}8857133\\ a&=250\ \lambda\ 2{\cdot}3979400 \end{aligned}\right\}\ \text{No. 130.}$$

$$\begin{aligned} \frac{1}{r}+\frac{1}{4}&=20{\cdot}25\ \lambda\ 1{\cdot}3064250\\ \text{V}&=3891{\cdot}15\ \lambda\ 3{\cdot}5900783 \end{aligned}$$

The value of the annuity will therefore in this case be L.3891. 3s.

132. *Ex.* 5. To what sum will an annuity of L.120 for 20 years amount, when each payment is improved at compound interest from the time of its becoming due until the expiration of the term, the rate of interest being 6 *per cent.?*

The operation by the second formula in No. 116 is thus:

$$\begin{aligned} 1+r&=1{\cdot}06\ \lambda\ 0{\cdot}025305865\\ &\qquad\times n=20\\ (1+r)^{n}&=3{\cdot}207135\ \lambda\ 0{\cdot}5061173\\ (1+r)^{n}-1&=2{\cdot}207135\ \lambda\ 0{\cdot}3438289\\ a&=120\ \lambda\ 2{\cdot}0791812\\ r&=\cdot06\ \varkappa\ 1{\cdot}2218487\\ \text{M}&=4414{\cdot}27\ \lambda\ 3{\cdot}6448588 \end{aligned}$$

And the amount required is L.4414. 5s. 5d.

133. *Ex.* 6. The rest being the same as in the last example; if both the interest and the annuity be payable half-yearly, the amount will be determined by the second of the formulæ given in No. 127, which in this case will become $\frac{120}{\cdot06}\left[(1{\cdot}03)^{40}-1\right]$, and the operation will be as follows:

$$\begin{aligned} 1{\cdot}03&\ \lambda\ 0{\cdot}01283723\\ &\qquad\times 40\\ (1{\cdot}03)^{40}&=3{\cdot}26204\ \lambda\ 0{\cdot}5134892\\ (1{\cdot}03)^{40}-1&=2{\cdot}26204\ \lambda\ 0{\cdot}3545003\\ &\qquad\lambda\ 2{\cdot}0791812\\ &\cdot06\ \varkappa\ 1{\cdot}2218487\\ \text{M}&=4524{\cdot}08\ \lambda\ 3{\cdot}6555302 \end{aligned}$$

So that the amount in this case would be L.4524. 1s. 7¼d.

Algebraical View.

II.—On the Probabilities of Life.

134. Any persons, A, B, C, &c. being proposed, let the numbers which tables of mortality (32) adapted to them represent to attain to their respective ages be denoted by the symbols a, b, c, &c.; while lives n years older than those respectively are denoted thus, ^{n}A, ^{n}B, ^{n}C, &c. and the numbers that attain to their ages, by the symbols ^{n}a, ^{n}b, ^{n}c, &c.; also let lives n years younger than A, B, C, &c. be denoted thus, A_n, B_n, C_n, &c., while the numbers which the tables show to attain to those younger ages are designated by the symbols a_n, b_n, c_n, &c.

Then, if A be 21 years of age, and we use the Carlisle table, we shall have $a = 6047$, and $^{14}a = 5362$, the number that attain to the age of 35, or that live to be 14 years older than A.

Hence the number that are represented by the table to die in n years from the age of A will be $a - {}^{n}a$, that is, in 14 years, $a - {}^{14}a$; and, by the Carlisle table, in 14 years from the age of 21, that is, between 21 and 35, it will be $6047 - 5362 = 685$.

135. *Problem.* To determine the probability that a proposed life A will survive n years.

Solution. a being the number of lives in the table of mortality attaining the age of that which is proposed, conceive that number of lives to be so selected (of which A must be one), that they may each have the same prospect with regard to longevity as the proposed life and those in the table, or the average of those from which it was constructed; then will the number of them that survive the term be ^{n}a. (134.)

So that the number of ways all equally probable, or the number of equal chances for the happening of the event in question, is ^{n}a; and the whole number for its either happening or failing is a; therefore, according to the first principles of the doctrine of probabilities, the probability of the event happening, that is, of A surviving the term, is $\frac{^{n}a}{a}$.

If the age of A be 14, the probability of that life surviving 7 years, or the age of 21, will, according to the Carlisle table, be $\frac{^{7}a}{a} = \frac{6047}{6335}$, or 0·95454.

136. Since the number that die in n years from the age of A is $a - {}^{n}a$ (134), it appears, in the same manner, that the probability of that life failing in n years will be $\frac{a - {}^{n}a}{a} = 1 - \frac{^{n}a}{a}$; which probability, when the life, term, and table of mortality are the same as in the last No., will be 0·04546.

137. If two lives A and B be proposed, since the probability of A surviving n years will be $\frac{^{n}a}{a}$, and that of B surviving the same term will be $\frac{^{n}b}{b}$, it appears from the doctrine of probabilities that $\frac{^{n}a}{a} \cdot \frac{^{n}b}{b}$ or $\frac{^{n}(ab)}{ab}$ will be the measure of the probability that these lives will both survive n years.

In the same manner it may be shown, that the probability of the three lives A, B, and C all surviving n years, will be measured by $\frac{^{n}a}{a} \cdot \frac{^{n}b}{b} \cdot \frac{^{n}c}{c}$, or $\frac{^{n}(abc)}{abc}$. And, universally, that any number of lives A, B, C, &c. will jointly survive n years, the probability is $\frac{^{n}(abc, \text{\&c.})}{abc, \text{\&c.}}$

138. Let $\frac{^{n}a}{a} = {}_{n}a$, $\frac{^{n}b}{b} = {}_{n}b$, $\frac{^{n}c}{c} = {}_{n}c$, &c.; also let $\frac{^{n}(abc, \text{\&c.})}{abc, \text{\&c.}} = {}_{n}(abc, \text{\&c.})$; so that the probabilities of A, B, C, &c. surviving n years may be denoted by ${}_{n}a$, ${}_{n}b$, ${}_{n}c$, &c. respectively; and that of all these lives jointly surviving that term by ${}_{n}(abc, \text{\&c.})$

Algebraical View.

Then will the probability that none of these lives will survive n years be $(1 - {}_{n}a) \cdot (1 - {}_{n}b) \cdot (1 - {}_{n}c) \cdot \text{\&c.}$

139. But the probability that some one or more of these lives will survive n years will be just what the probability last mentioned is deficient of certainty: its measure, therefore, being just what the measure of that probability is deficient of unit, will be

$$1 - (1 - {}_{n}a) \cdot (1 - {}_{n}b) \cdot (1 - {}_{n}c) \cdot \text{\&c.}$$

140. *Corol.* 1. When there is only one life A, this will be ${}_{n}a$.

141. *Corol.* 2. When there are two lives A and B, it becomes ${}_{n}a + {}_{n}b - {}_{n}(ab)$.

142. *Corol.* 3. When there are three lives A, B, and C, it becomes ${}_{n}a + {}_{n}b + {}_{n}c - {}_{n}(ab) - {}_{n}(ac) - {}_{n}(bc) + {}_{n}(abc)$.

143. When three lives A, B, and C are proposed, that at the expiration of n years there will be

living	dead	the probability is
ABC	none	.... $+ {}_{n}(abc)$
AB	C	${}_{n}(ab) \cdot (1 - {}_{n}c) = {}_{n}(ab) - {}_{n}(abc)$
AC	B	${}_{n}(ac) \cdot (1 - {}_{n}b) = {}_{n}(ac) - {}_{n}(abc)$
BC	A	${}_{n}(bc) \cdot (1 - {}_{n}a) = {}_{n}(bc) - {}_{n}(abc)$

And the sum of these four ${}_{n}(ab) + {}_{n}(ac) + {}_{n}(bc) - 2{}_{n}(abc)$, is the measure of the probability that some two at the least out of these three lives will survive the term.

III.—Of Annuities on Lives.

144. Let the number of years' purchase that an annuity on the life of A is worth, that is, the present value of L.1 to be received at the end of every year during the continuance of that life, be denoted by A; while the present value of an annuity on any number of joint lives A, B, C, &c. that is, of an annuity which is to continue during the joint existence of all the lives, but to cease with the first that fails, is denoted by ABC, &c.

Then will the value of an annuity on the joint continuance of the three lives A, B, and C, be denoted by ABC.

And on the joint continuance of the two A and B, by AB.

145. Also let ^{t}A and A$_{t}$ denote the values of annuities on lives respectively older and younger than A, by t years; while ^{t}(ABC, &c.) designates the value of an annuity on the joint continuance of lives t years older than A, B, C, &c. respectively; and (ABC, &c.)$_{t}$ that of an annuity on the same number of joint lives, as many years younger than these respectively.

146. Let $\frac{1}{1+r}$, the present value of L.1 to be received certainly at the expiration of a year, be denoted by v.

Then will v^n be the present value of that sum certain to be received at the expiration of n years.

But if its receipt at the end of that time be dependent upon an assigned life A surviving the term, its present value will, by that condition, be reduced in the ratio of certainty to the probability of A surviving the term, that is, in the ratio of unit to ${}_{n}a$, and will therefore be ${}_{n}av^n$.

In the same manner it appears, that if the receipt of the money at the expiration of the term be dependent upon any assigned lives, as A, B, C, &c. jointly surviving that period, its present value will be ${}_{n}(abc, \text{\&c.})v^n$.

Algebraical View.

147. Let us denote the sum of any series, as ${}_1(abc)v + {}_2(abc)v^2 + {}_3(abc)v^3 +$ &c. thus, $S_n(abc)v^n$, by prefixing the Italic capital S to the general term thereof. Then, from what has just been advanced, it will be evident that ABC, &c. $= S_n(abc, \&c.)v^n$.

When there are but three lives, A, B, and C, this becomes ABC $= S_n(abc)v^n$.

When there are but two, A and B, it becomes AB $= S_n(ab)v^n$.

And in the same manner it appears, that for a single life A, A $= S_n av^n$.

148. ${}_n(abc, \&c.)v^n = \dfrac{{}^n(abc, \&c.)v^n}{abc, \&c.}$ (138), where the denominator (abc, &c.) is constant, while the numerator varies with the variable exponent n. And the most obvious method of finding the value of an annuity on any assigned single or joint lives, is to calculate the numerical value of the term ${}^n(abc, \&c.)v^n$ for each value of n, and then to divide the sum of all these values by abc, &c.; for $\dfrac{S^n(abc, \&c.)v^n}{abc, \&c.} = S_n(abc, \&c.)v^n =$ ABC, &c.

In calculating a table of the values of annuities on lives in that manner, for every combination of joint lives it would be necessary to calculate the term ${}^n(abc, \&c.)v^n$ for as many years as there might be between the age of the oldest life involved and the oldest in the table; and the same number of the terms ${}^nav^n$ for any single life of the same age.

But this labour may be greatly abridged as follows:

PROB. I.

149. Given ${}'$(ABC, &c.), the value of an annuity on any number of joint lives, to determine ABC, &c. that of an annuity on the same number of joint lives respectively one year younger than they.

Solution.

If it were certain that the lives ABC, &c. would all survive one year, the proprietor of an annuity of L.1 dependent upon their joint continuance would, at the expiration of a year, be in possession of L.1 (the first year's rent), and an annuity on the same number of lives one year older respectively than ABC, &c.; therefore, in that case, the required present value of the annuity would be $v[1 + {}'$(ABC, &c.)$]$. (146.)

But the probability of the lives A, B, C, &c. jointly surviving one year is less than certainty in the ratio of ${}_{\prime}(abc$, &c.) to unit; therefore ABC, &c. $= {}_{\prime}(abc$, &c.) $v[1 + {}'$(ABC, &c.)$]$.

150. *Corol.* 1. When there are but three lives, A, B, and C, this becomes ABC $= {}_{\prime}(abc)v[1 + {}'(ABC)]$.

151. *Corol.* 2. When there are only two, A and B, AB $= {}_{\prime}(ab)v[1 + {}'(AB)]$.

152. *Corol.* 3. And for a single life A, it appears, in the same manner, that A $= {}_{\prime}av(1 + {}'$A).

153. Hence, in logarithms, we have these equations,

$$\lambda \text{A} = \lambda v + \lambda {}_{\prime}a + \lambda(1 + {}'\text{A}),$$
$$\lambda \text{AB} = \lambda v + \lambda {}_{\prime}a + \lambda {}_{\prime}b + \lambda[1 + {}'(\text{AB})],$$
$$\lambda \text{ABC} = \lambda v + \lambda {}_{\prime}a + \lambda {}_{\prime}b + \lambda {}_{\prime}c + \lambda[1 + {}'(\text{ABC})],$$
&c. &c. &c.

Upon which it may be observed, that $\lambda v + \lambda {}_{\prime}a$, the sum of the first two logarithms that are employed in determining A from ${}'$A, also enters the operation whereby AB is determined from ${}'$(AB). And that $\lambda v + \lambda {}_{\prime}a + \lambda {}_{\prime}b$, the sum of the first three logarithms that serve to determine AB from ${}'$(AB), is also required to determine ABC from ${}'$(ABC); which observation may be extended in a similar manner to any greater number of joint lives.

154. By these means it is easy to complete a table of the values of annuities on single lives of all ages, beginning with the oldest in the table, and proceeding regularly age by age to the youngest.

Algebraical View.

Also a table of the values of any number of joint lives, the lives in each succeeding combination, in any one series of operations (according to the retrograde order of the ages in which they are computed), being one year younger respectively than those in the preceding combination.

And, if a table of single lives be computed first, then of two joint lives, next of three joint lives, and so on, the calculations made for the preceding tables will be of great use for the succeeding.

155. Having shown how to compute tables of the values of annuities on single and joint lives, we shall, in what follows, always suppose those values to be given.

156. Let the value of an annuity on the joint continuance of any number of lives, A, B, C, &c. that is not to be entered upon until the expiration of t years, be denoted by $\neg^t$(ABC, &c.).

Then, if it were certain that all the lives would survive the term, since the value of the annuity at the expiration of the term would be ^{t}(ABC, &c.) (145), its present value would be $v^t . {}^t$(ABC, &c.) (146).

But the measure of the probability that all the lives will survive the term is ${}_t(abc$, &c.), therefore $\neg^t$(ABC, &c.) $= {}_t(abc$, &c.) $v^t . {}^t$(ABC, &c.).

In the same manner, it appears, that for a single life A, $\neg^t$A $= {}_tav^t . {}^t$A.

157. Let an annuity for the term of t years only, dependent upon the joint continuance of any number of lives, A, B, C, &c. be denoted by $\underset{t|}{-}$(ABC, &c.); and, since this *temporary* annuity, together with an annuity on the joint continuance of the same lives *deferred* for the same term, will evidently be of the same value as an annuity to be entered upon immediately, and enjoyed during their whole joint continuance, we have $\underset{t|}{-}$(ABC, &c.) $+ \neg^t$ (ABC, &c.) $=$ ABC, &c.; whence, $\underset{t|}{-}$(ABC, &c.) $=$ ABC, &c. $- \neg$ (ABC, &c.).

And for a single life A, $\underset{t|}{-}$A $=$ A $- \neg^t$A.

PROB. II.

158. To determine the present value of an annuity on the survivor of the two lives A and B (155); which we designate thus, $\overline{\text{AB}}$.

Solution.

The probability that the survivor of these two lives will outlive the term of n years was shown in No. 141 to be ${}_na + {}_nb - {}_n(ab)$; therefore, reasoning as in No. 146, it will be found that the present value of the nth year's rent of this annuity is $[{}_na + b - {}_n(ab)]v^n$, and the value of all the rents thereof will be $S[{}_na + {}_nb - {}_n(ab)]v^n$, or $S_nav^n + S_nbv^n - S_n(ab)\ v^n$; so that $\overline{\text{AB}} =$ A $+$ B $-$ AB (147), agreeably to No. 48.

PROB. III.

159. To determine the present value of an annuity on the last survivor of three lives, A, B, and C (155); which we denote thus, $\overline{\text{ABC}}$.

Solution.

The present value of the nth year's rent is $[{}_na + {}_nb + {}_nc - {}_n(ab) - {}_n(ac) - {}_n(bc) + {}_n(abc)]v^n$ (142 and 146); whence, it appears, as in the preceding number, that $\overline{\text{ABC}} =$ A $+$ B $+$ C $-$ AB $-$ AC $-$ BC $+$ ABC, agreeably to No. 52.

Algebraical View.

PROB. IV.

160. To determine the present value of an annuity on the joint existence of the last two survivors out of three lives, A, B, C, (155); which we denote thus, $\overset{2}{\overline{\text{ABC}}}$.

Solution.

The present value of the nth year's rent is $[_n(ab) + {_n(ac)} + {_n(bc)} - 2_n(abc)]v^n$ (143 and 146); whence, reasoning as in the two preceding numbers, we infer, that $\overset{2}{\overline{\text{ABC}}} = \text{AB} + \text{AC} + \text{BC} - 2\ \text{ABC}$, as was demonstrated otherwise in No. 51.

161. Since the solutions of the last three problems were all obtained by showing each year's rent (as for instance the nth) of the annuity in question to be of the same value with the aggregate of the rents for the same year of all the annuities (taken with their proper signs) on the single and joint lives exhibited in the resulting formula; if any term of years be assigned, it is manifest that the value of such annuity for the term must be the same as that of the aggregate of the annuities above mentioned, each for the same term.

PROB. V.

162. A and B being any two proposed lives now both existing, to determine the present value of an annuity receivable only while A survives B.

Solution.

A rent of this annuity will only be payable at the end of the nth year, provided that B be then dead and A living; but the probability of B being then dead is $1 - {_nb}$, and that of A being then living $_na$, and these two events are independent; therefore, the probability of their both happening, or that of the rent being received, is $(1 - {_nb})\,{_na} = {_na} - {_n(ab)}$; the present value of that rent is, therefore, $[_na - {_n(ab)}]v^n$; whence it follows, that the required value of the annuity on the life of A after that of B is $\text{A} - \text{AB}$, agreeably to No. 60.

163. If the payment for the annuity which was the subject of the last problem is not to be made in present money, but by a constant annual premium p at the end of each year, while both the lives survive; since AB is the number of years' purchase (6) that an annuity on the joint continuance of those lives is worth, the value of p will be determined by this equation, $\text{p} \cdot \text{AB} = \text{A} - \text{AB}$, whence we have $\text{p} = \frac{\text{A}}{\text{AB}} - 1$.

164. But if one premium p is to be paid down now, and an equal premium at the end of each year while both the lives survive, we shall have $p \cdot (1 + \text{AB}) = \text{A} - \text{AB}$, and $p = \frac{\text{A} - \text{AB}}{1 + \text{AB}}$.

165. For numerical examples illustrative of the formulæ given from No. 158 to the present, see Nos. 66–74.

PROB. VI.

166. A and B are in possession of an annuity on the life of the survivor of them, which, if either of them die before a third person C, is then to be divided equally between C and the survivor during their joint lives; to determine the value of C's interest.

Solution.

That at the end of the nth year there will be dead	living	the probability, multiplied by C's proportion of the annuity in that circumstance, is
A	BC	$\frac{1}{2}(1 - {_na}) \cdot {_n(bc)} = \frac{1}{2}[_n(bc) - {_n(abc)}]$
B	AC	$\frac{1}{2}(1 - {_nb}) \cdot {_n(ac)} = \frac{1}{2}[_n(ac) - {_n(abc)}]$;

and the sum of these being $\frac{1}{2}{_n(ac)} + \frac{1}{2}{_n(bc)} - {_n(abc)}$, the value of C's interest is $\frac{1}{2}\,\text{AC} + \frac{1}{2}\,\text{BC} - \text{ABC}$.

Algebraical View.

PROB. VII.

167. An annuity, after the decease of A, is to be equally divided between B and C during their joint lives, and is then to go entirely to the last survivor for his life; it is proposed to find the value of B's interest therein.

Solution.

That at the end of the nth year there will be dead	living	the probability, multiplied by B's proportion of the annuity in that circumstance, is
A	BC	...........$+ \frac{1}{2}{_n(bc)} - \frac{1}{2}{_n(abc)}$
AC	B	${_nb} - {_n(ab)} - {_n(bc)} + {_n(abc)}$; and the sum

of these being ${_nb} - {_n(ab)} - \frac{1}{2}{_n(bc)} + \frac{1}{2}{_n(abc)}$, the value of B's interest is $\text{B} - \text{AB} - \frac{1}{2}\,\text{BC} + \frac{1}{2}\,\text{ABC}$.

PROB. VIII.

168. A, B, and C purchase an annuity on the life of the last survivor of them, which is to be divided equally at the end of every year among such of them as may then be living; what should A contribute towards the purchase of this annuity?

Solution.

That at the end of n years there will be dead	living	the probability, multiplied by A's proportion of the annuity in that circumstance, is
none	ABC	....................$+ \frac{1}{3}{_n(abc)}$
C	AB	....$+ \frac{1}{2}{_n(ab)}$......$- \frac{1}{2}{_n(abc)}$
B	AC	.........$+ \frac{1}{2}{_n(ac)} - \frac{1}{2}{_n(abc)}$
BC	A	${_na} - {_n(ab)} - {_n(ac)} + {_n(abc)}$; and the sum

of these being ${_na} - \frac{1}{2}{_n(ab)} - \frac{1}{2}{_n(ac)} + \frac{1}{3}{_n(abc)}$, the required value of A's interest is $\text{A} - \frac{1}{2}\,\text{AB} - \frac{1}{2}\,\text{AC} + \frac{1}{3}\,\text{ABC}$.

PROB. IX.

169. As soon as any two of the three lives, A, B, and C, are extinct, D or his heirs are to enter upon an annuity, which they are to enjoy during the remainder of the survivor's life; to determine the value of D's interest therein.

Solution.

That at the end of n years there will be dead	living	The probability is
AB	C	${_nc} - {_n(ac)} - {_n(bc)} + {_n(abc)}$
AC	B	${_nb} - {_n(ab)} - {_n(bc)} + {_n(abc)}$
BC	A	${_na} - {_n(ab)} - {_n(ac)} + {_n(abc)}$; and the sum

of all these being ${_na} + {_nb} + {_nc} - 2_n(ab) - 2_n(ac) - 2_n(bc) + 3_n(abc)$, the value of D's interest is

$$\text{A} + \text{B} + \text{C} - 2\ \text{AB} - 2\ \text{AC} - 2\ \text{BC} + 3\ \text{ABC}.$$

170. The last four may be sufficient to show the method of proceeding with any similar problems.

171. Let ${_t}\left(\overset{m}{\overline{abc,\ \&c.}}\right)$ denote the probability that the last m survivors out of $m + \mu$ lives A, B, C, &c. will jointly survive the term of t years. And when $\mu = 0$, the expression will become ${_t}(abc,\ \&c.)$, the probability that the lives will all survive the term. (138.)

When $m = 1$ it will become ${_t}\left(\overset{1}{\overline{abc,\ \&c.}}\right)$, the measure of

Algebraical View.

the probability that the last survivor of them will outlive the term, which it will be better to write thus, ${}_t(\overline{abc, \&c.})$, retaining the vinculum, but omitting the unit over it, as in the notation of powers.

Also let $\overline{\overset{m}{\text{ABC, \&c.}}}$ denote the value of an annuity on the joint continuance of the same number of last survivors out of the same lives. Then, if μ be equal to 0, it will be ABC, &c. the value of an annuity on the joint continuance of all the lives; when $m=1$, it will be $\overline{\text{ABC, \&c.}}$ the value of an annuity on the last survivor of them. The values of annuities on the last survivor of two and of three lives will be denoted as in Nos. 158 and 159 respectively; and that of an annuity on the joint continuance of the last two survivors out of three lives, as in No. 160.

The value of an annuity on the last m survivors out of these $m+\mu$ lives, according as it is limited to the term of t years, or deferred during that term, will also be denoted by $\underset{t|}{}\overline{\overset{m}{\text{ABC, \&c.}}}$ or $\underset{|}{}{}_t\overline{\overset{m}{\text{ABC, \&c.}}}$ (156 and 157.)

PROB. X.

172. An annuity certain for the term of $t+\nu$ years is to be enjoyed by P and his heirs during the joint existence of the last m survivors out of $m+\mu$ lives, A, B, C, &c.; and if that joint existence fail before the expiration of t years, the annuity is to go to Q and his heirs for the remainder of the term; to determine the value of Q's interest in that annuity.

Solution.

Q's expectation may be distinguished into two parts:

1*st*, That of enjoying the annuity during the term of t years.

2*d*, That of enjoying it after the expiration of that term.

The sum of the present values of the interests of P and Q together in the annuity for the term of t years, is manifestly equal to the whole present value of the annuity certain for that term; that is, equal to $\frac{1-v^t}{r}$ (113 and 146); and the value of P's interest for the term of t years is $\underset{t|}{}\overline{\overset{m}{\text{ABC, \&c.}}}$ (171); therefore the value of Q's interest for the same term is $\frac{1-v^t}{r} - \underset{t|}{}\overline{\overset{m}{\text{ABC, \&c.}}}$

The present value of the annuity certain for ν years after t years is $\frac{v^t(1-v^\nu)}{r}$ (114 and 146); and Q and his heirs will receive this annuity if the joint continuance of the last m survivors above mentioned fail before the expiration of t years; but the probability of their joint continuance failing in the term is $1-{}_t\left(\overline{\overset{m}{abc, \&c.}}\right)$; therefore the value of Q's interest in the annuity to be received after t years, is $\left[1-{}_t\left(\overline{\overset{m}{abc, \&c.}}\right)\right]\frac{v^t(1-v^\nu)}{r}$; and the whole value of Q's interest is

$$\frac{1}{r}\left[1-v^{\nu+t}-v^t(1-v^\nu)\cdot{}_t\left(\overline{\overset{m}{abc, \&c.}}\right)\right] - \underset{t|}{}\overline{\overset{m}{\text{ABC, \&c.}}}$$

173. *Corol.* 1. When the whole annuity certain is a perpetuity, $v^{t+\nu}=0$, and the value of Q's interest is

$$\frac{1}{r}\left[1-{}_t\left(\overline{\overset{m}{abc, \&c.}}\right)v^t\right] - \underset{t|}{}\overline{\overset{m}{\text{ABC, \&c}}}$$

174. *Corol.* 2 When the term t is not less than the greatest joint continuance of any m of the proposed lives, according to the tables of mortality adapted to them, ${}_t\left(\overline{\overset{m}{abc, \&c.}}\right)=0$, and $\underset{t|}{}\overline{\overset{m}{\text{ABC, \&c.}}} = \overline{\overset{m}{\text{ABC, \&c.}}}$; therefore, in that case, the general formula of No. 172 becomes $\frac{1-v^{\nu+t}}{r} - \overline{\overset{m}{\text{ABC, \&c.}}}$; that is, the excess of the value of an annuity certain for the whole term $\nu+t$, above that of an annuity on the whole duration of joint continuance of the last m surviving lives.

175. And if, in the case proposed in the last No., the annuity certain be a perpetuity, as in No. 173, the formula will become $\frac{1}{r} - \overline{\overset{m}{\text{ABC, \&c.}}}$ the excess of the value of the perpetuity above the value of an annuity on the joint lives of the last m survivors; agreeably to No. 63.

176. *Example* 1. Required the present value of the absolute reversion of an estate in fee simple, after the extinction of the last survivor of three lives, A, B, C, now aged 50, 55, and 60 years respectively; reckoning interest at 5 *per cent.*

The general algebraical expression of this value has just been shown to be $\frac{1}{r} - \overline{\text{ABC.}}$

$$\text{But } \frac{1}{r} = \frac{1}{0{\cdot}5} = 20{\cdot}000$$
$$\text{And } \overline{\text{ABC,}} \quad = 14{\cdot}001 \text{ (68.)}$$

Therefore 5·999 years' purchase is the value required. And if the annual produce of the estate, clear of all deductions, were L.100, the title to the reversion would now be worth L.599. 18s. —, agreeably to No. 76.

177. *Ex.* 2. An annuity for the term of 70 years certain (from this time) is to revert to Q and his heirs at the failure of a life A, now 45 years of age; what is the present value of Q's interest therein, reckoning the interest of money at 5 *per cent.?*

In No. 174 the algebraical expression of the required value is shown to be $\frac{1-v^{70}}{r} - \text{A}$.

$$\text{But } \lambda v = \text{ʌ } 1{\cdot}05 = \bar{1}{\cdot}9788107$$
$$\times\ 70$$
$$v^{70} = {\cdot}032866\,\lambda\,\bar{2}{\cdot}5167490$$
$$1-v^{70} = {\cdot}967134$$
$$\frac{1-v^{70}}{r} = \frac{{\cdot}967134}{{\cdot}05} = 19{\cdot}34268$$
$$\text{Subtract A} = 12{\cdot}64800 \text{ (Tab. VI.)}$$

remains 6·69468 years' purchase; so that if the annuity were L.1000, the value of the reversion would be L.6694. 13s. 7d.

178. *Ex.* 3. An annuity for the term of 70 years certain from this time is to revert to Q and his heirs at the extinction of the survivor of two lives, A and B, now aged 40 and 50 years respectively, the interest of money being 5 *per cent.*; it is required to determine the value of Q's interest in this annuity.

The algebraical expression of the value is, $\frac{1-v^{70}}{r} - \overline{\text{AB}}$ (174 and 171).

$$\text{But by the last example } \frac{1-v^{70}}{r} = 19{\cdot}34268$$
$$\text{and by No. 66, } \overline{\text{AB}} = 15{\cdot}06600$$

so that the required value is 4·27668 years'

Algebraical View.

purchase; and if the annuity be L.1000, the present value of the reversion will be L.4276. 13s. 7d.

IV.—Of Assurances on Lives.

179. Let the present value of the assurance (77 and 78) of L.1 on the life of A be denoted by the old English capital $\mathfrak{A}$, and that of an assurance on the joint continuance of any number of lives A, B, C, &c. by $\mathfrak{ABC}$, &c. Also, let the value of an assurance on the joint continuance of any m of them out of the whole number $m+\mu$ be denoted by $\overset{m}{\overline{\mathfrak{ABC}, \&c.}}$

180. And, in every case, let us designate the annual premium (83) for an assurance, by prefixing the character $\odot$ to the symbol for the single premium; so that $\odot\mathfrak{A}$ may denote the annual premium for an assurance on the life of A; $\odot\mathfrak{ABC}$, &c. the same for an assurance on the joint continuance of all the lives, A, B, C, &c.; and $\odot\,\overset{m}{\overline{\mathfrak{ABC}, \&c.}}$ the annual premium for an assurance on the joint continuance of the last m survivors out of the whole number $m+\mu$ of those lives.

181. Then will ${}_{t|}\mathfrak{A}$ and $\odot\,{}_{t|}\mathfrak{A}$, ${}_{t|}\mathfrak{ABC}$, &c. and $\odot\,{}_{t|}\mathfrak{ABC}$, &c., ${}_{t|}\overset{m}{\overline{\mathfrak{ABC}, \&c.}}$ and $\odot\,{}_{t|}\overset{m}{\overline{\mathfrak{ABC}, \&c.}}$ designate the single and annual premiums for assurances on the same life or lives for the term of t years only.

Prob. XI.

182. To determine $\left({}_{t|}\overset{m}{\overline{\mathfrak{ABC}, \&c.}}\right)$ the present value of an assurance on the last m survivors out of $m+\mu$ lives A, B, C, &c. for the term of t years only; that is, the present value of L.1 to be received upon the joint continuance of these last m survivors failing in the term.

Solution.

By reasoning as in No. 79, it will be found that a perpetuity, the first payment of which is to be made at the end of the year in which the last m survivors out of these $m+\mu$ lives may fail in the term, will be of the same present value as $\left(1+\frac{1}{r}=\right)\frac{1}{1-v}$ pounds to be received in the same event (112 and 146); but, in No. 173, the value of the reversion of such a perpetuity in that event was shown to be $\frac{v}{1-v}\left[1-{}_t\overset{m}{\overline{(abc, \&c.)}}v^t\right]-{}_{t|}\overset{m}{\overline{\text{ABC}, \&c.}}$

whence it is manifest that ${}_{t|}\overset{m}{\overline{\mathfrak{ABC}, \&c.}}$

$$= v\left[1-{}_t\overset{m}{\overline{(abc, \&c.)}}\,v^t\right]-(1-v)\;{}_{t|}\overset{m}{\overline{\text{ABC}, \&c.}}$$

183. Since the annual premium for this assurance must be paid at the commencement of every year in the term, while the last m surviving lives all subsist (83); besides the premium paid down now, one must be paid at the expiration of every year in the term except the last, provided that these last m survivors all outlive it; but the present value of L.1 to be received upon their surviving that last year is ${}_t\overset{m}{\overline{(abc, \&c.)}}v^t$, therefore all the future premiums are now worth ${}_{t|}\overset{m}{\overline{\text{ABC}, \&c.}}-{}_t\overset{m}{\overline{(abc, \&c.)}}\,v^t$ years' purchase, and the present value of all the premiums, or the total present value of the assurance, is

Algebraical View.

$$\odot\,{}_{t|}\overset{m}{\overline{\mathfrak{ABC}, \&c.}}\left[1-{}_t\overset{m}{\overline{(abc, \&c.)}}\,v^t+{}_{t|}\overset{m}{\overline{\text{ABC}, \&c.}}\right]=$$

$$v\left[1-{}_t\overset{m}{\overline{(abc,\&c.)}}v^t\right]-(1-v)\,{}_{t|}\overset{m}{\overline{\text{ABC},\&c.}}=1-{}_t\overset{m}{\overline{(abc,\&c.)}}v^t$$

$$-(1-v)\cdot\left[1-{}_t\overset{m}{\overline{(abc, \&c.)}}v^t+{}_{t|}\overset{m}{\overline{\text{ABC}, \&c.}}\right],$$ whence we have

$$\odot\,{}_{t|}\overset{m}{\overline{\mathfrak{ABC}, \&c.}}=\frac{1-{}_t\overset{m}{\overline{(abc, \&c.)}}\,v^t}{1-{}_t\overset{m}{\overline{(abc, \&c.)}}v^t+{}_{t|}\overset{m}{\overline{\text{ABC}, \&c.}}}+v-1.$$

184. *Corol.* 1. When (t), the term of the assurance, is not less than the greatest possible joint duration of any m of the proposed lives, ${}_t\overset{m}{\overline{(abc, \&c.)}}=0$, ${}_{t|}\overset{m}{\overline{\text{ABC}, \&c.}}=\overset{m}{\overline{\text{ABC}, \&c.}}$, and the general formulæ of the two preceding numbers become respectively

$$\overset{m}{\overline{\mathfrak{ABC}, \&c.}}=v-(1-v)\,\overset{m}{\overline{\text{ABC}, \&c.}}$$

$$\text{and }\odot\,\overset{m}{\overline{\mathfrak{ABC}, \&c.}}=\frac{1}{1+\overset{m}{\overline{\text{ABC}, \&c.}}}+v-1.$$

185. *Corol.* 2. In the same manner it appears, that, for a single life, $\mathfrak{A}=v-(1-v)\,\text{A}$,

$$\text{and }\odot\mathfrak{A}=\frac{1}{1+\text{A}}+v-1.$$

186. *Corol.* 3. Also that ${}_{t|}\mathfrak{A}=v\,(1-{}_ta\,v^t)-(1-v)\,{}_{t|}\text{A}$

$$\text{or }{}_{t|}\mathfrak{A}=v\left(1-\frac{{}^ta}{a}v^t\right)-(1-v)\cdot\left(\text{A}-\frac{{}^ta}{a}v^t\cdot{}^t\text{A}\right).$$

$$\text{And }\odot\,{}_{t|}\mathfrak{A}=\frac{1-{}_tav^t}{1-{}_ta\,v^t+{}_{t|}\text{A}}+v-1;$$

$$\text{that is, }\odot\,{}_{t|}\mathfrak{A}=\frac{1-\frac{{}^ta}{a}v^t}{1+\text{A}-\frac{{}^ta}{a}v^t\cdot(1+{}^t\text{A})}+v-1.$$

187. *Corol.* 4. When the assurance is on the joint continuance of all the lives, the formulæ of No. 184 become respectively

$$\mathfrak{ABC},\ \&c. = v-(1-v)\ \text{ABC},\ \&c.$$

$$\text{and }\odot\,\mathfrak{ABC},\ \&c.=\frac{1}{1+\text{ABC},\ \&c.}+v-1.$$

And those of numbers 182 and 183,

$${}_{t|}\mathfrak{ABC},\ \&c.=v\left(1-\frac{{}^t(abc,\ \&c.)}{abc,\ \&c.}v^t\right)-(1-v)\times\left[\text{ABC},\ \&c.-\frac{{}^t(abc,\ \&c.)}{abc,\ \&c.}v^t\cdot{}^t(\text{ABC},\ \&c.)\right]$$

and $\odot\,{}_{t|}\mathfrak{ABC}$, &c. =

$$\frac{1-\frac{{}^t(abc,\ \&c.)}{abc,\ \&c.}v^t}{1+\text{ABC},\ \&c.-\frac{{}^t(abc,\ \&c.)}{abc,\ \&c.}v^t\left[1+{}^t(\text{ABC},\ \&c.)\right]},$$

$+v-1.$

188. *Corol.* 5. According as the assurance is in the last survivor of two or of three lives, the formulæ of No. 184 become respectively

Algebraical View.

$$\overline{\mathfrak{AB}} = v-(1-v)\,\overline{\text{AB}},$$

$$\text{and } \odot\,\overline{\mathfrak{AB}} = \frac{1}{1+\overline{\text{AB}}}+v-1;$$

$$\text{or } \overline{\mathfrak{ABC}} = v-(1-v)\,\overline{\text{ABC}},$$

$$\text{and } \odot\,\overline{\mathfrak{ABC}} = \frac{1}{1+\overline{\text{ABC}}}+v-1.$$

And those of numbers 182 and 183 become

$$_{\overline{t|}}\overline{\mathfrak{AB}} = v\left[1-{}_t\overline{(ab)}v^t\right]-(1-v)\,{}_{\overline{t|}}\overline{\text{AB}},$$

$$\text{and } \odot\,{}_{\overline{t|}}\overline{\mathfrak{AB}} = \frac{1-{}_t\overline{(ab)}v^t}{1-{}_t\overline{(ab)}v^t+{}_{\overline{t|}}\overline{\text{AB}}}+v-1;$$

$$\text{or } {}_{\overline{t|}}\overline{\mathfrak{ABC}} = v\left[1-{}_t\overline{(abc)}v^t\right]-(1-v)\,{}_{\overline{t|}}\overline{\text{ABC}},$$

$$\text{and } \odot\,{}_{\overline{t|}}\overline{\mathfrak{ABC}} = \frac{1-{}_t\overline{(abc)}v^t}{1-{}_t\overline{(abc)}v^t+{}_{\overline{t|}}\overline{\text{ABC}}}+v-1 \text{ respec-}$$

tively.

Where ${}_t\overline{(ab)} = {}_ta+{}_tb-{}_t(ab)$ (141),

and ${}_t\overline{(abc)} = {}_ta+{}_tb+{}_tc-\left[{}_t(ab)+{}_t(ac)+{}_t(bc)\right]+{}_t(abc)$. (142.)

For the values of $\overline{\text{AB}}$, $\overline{\text{ABC}}$, ${}_{\overline{t|}}\overline{\text{AB}}$, and ${}_{\overline{t|}}\overline{\text{ABC}}$, see numbers 157–159, and 161.

189. *Corol.* 6. When the assurance is on the joint continuance of the two last survivors out of the three lives *A*, *B*, *C*, the formulæ of No. 184 become respectively

$$\overset{2}{\overline{\mathfrak{ABC}}} = v-(1-v)\,\overset{2}{\overline{\text{ABC}}},$$

$$\text{and } \odot\,\overset{2}{\overline{\mathfrak{ABC}}} = \frac{1}{1+\overset{2}{\overline{\text{ABC}}}}+v-1.$$

Those of numbers 182 and 183,

$${}_{\overline{t|}}\overset{2}{\overline{\mathfrak{ABC}}} = v\left[1-{}_t\overset{2}{\overline{(abc)}}\,v^t\right]-(1-v)\,{}_{\overline{t|}}\overset{2}{\overline{\text{ABC}}},$$

$$\text{and } \odot\,{}_{\overline{t|}}\overset{2}{\overline{\mathfrak{ABC}}} = \frac{1-{}_t\overset{2}{\overline{(abc)}}v^t}{1-{}_t\overset{2}{\overline{(abc)}}v^t+{}_{\overline{t|}}\overset{2}{\overline{\text{ABC}}}}+v-1.$$

Where ${}_t\overset{2}{\overline{(abc)}} = {}_t(ab)+{}_t(ac)+{}_t(bc)-2\,{}_t(abc)$. (143.)

For the values of $\overset{2}{\overline{\text{ABC}}}$ and ${}_{\overline{t|}}\overset{2}{\overline{\text{ABC}}}$ see numbers 157, 160, and 161.

190. $v\left[1-{}_t\overset{m}{\overline{(abc,\ \&c.)}}v^t\right]-(1-v)\,{}_{\overline{t|}}\overset{m}{\overline{\text{ABC, \&c.}}}$ the value of an assurance on any life or lives for the term of *t* years, which was given in No. 182, may also be expressed thus:

$$\left[1+{}_{\overline{t|}}\overset{m}{\overline{(\text{ABC, \&c.})}}-{}_t\overset{m}{\overline{(abc,\ \&c.)}}v^t\right]v-{}_{\overline{t|}}\overset{m}{\overline{\text{ABC, \&c.}}}$$

And this, in words at length, is the rule given in No. 93.

191. When *t* is not less than the greatest possible joint duration of any *m* of the proposed lives, the last expression becomes

$$\left(1+\overset{m}{\overline{\text{ABC, \&c.}}}\right)v-\overset{m}{\overline{\text{ABC, \&c.}}}$$

which is also equivalent to the first in No. 184; and, in words at length, is the rule given in No. 97 for determining the value of an assurance on any life or lives for their whole duration.

192. By substituting $\frac{1}{1+r}$ for v (146) in the last expression, it becomes $\frac{1+\overset{m}{\overline{\text{ABC, \&c.}}}}{1+r}-\overset{m}{\overline{\text{ABC, \&c.}}}$

$$=\frac{1-r.\overset{m}{\overline{\text{ABC, \&c.}}}}{1+r}, \text{ or } \frac{\frac{1}{r}-\overset{m}{\overline{\text{ABC, \&c.}}}}{1+\frac{1}{r}}. \text{ And}$$

$$\frac{\frac{1}{r}-\overset{m}{\overline{\text{ABC, \&c.}}}}{1+\frac{1}{r}} = \overset{m}{\overline{\mathfrak{ABC}, \&c.}}$$ is the proposition enunciated in No. 81; $\frac{1}{r}$ being the value of the perpetuity. (112.)

193. Examples of the determination of the single premiums for assurances, and of the derivation of the annual premiums from them, have been given in No. 82–88, also in 95 and 96; but by the algebraical formulæ given here, the annual premiums may be determined directly, without first finding the total present values of the assurances.

194. *Example* 1. Required the annual premium for an assurance on the life *A*, now 50 years of age, interest 5 *per cent.*

According to No. 185, the operation is thus,

$$\left.\begin{aligned} 1+\text{A} &= 12{\cdot}660\ \lambda \\ \frac{1}{1+\text{A}} &= {\cdot}0789890\ \varkappa \end{aligned}\right\}\bar{2}{\cdot}8975663$$

adding $v = {\cdot}9523809$, and subtracting unit,

we have $\odot\,\mathfrak{A}$ ·0313699, agreeably to No. 85.

195. *Ex.* 2. What should the annual premium be for an assurance on the last survivor of three lives *A*, *B*, and *C*, now aged 50, 55, and 60 years respectively, rate of interest 5 *per cent.?*

Operation by No. 188.

$$\left.\begin{aligned} (68)\ 1+\overline{\text{ABC}} &= 15{\cdot}001\ \lambda \\ \frac{1}{1+\overline{\text{ABC}}} &= {\cdot}0666622\ \varkappa \end{aligned}\right\}\bar{2}{\cdot}8238798$$

$$v = {\cdot}9523809$$

$$\odot\,\overline{\mathfrak{ABC}} = {\cdot}0190431, \text{ agreeably to No. 88.}$$

196. *Ex.* 3. Required the annual premium for an assurance for 10 years only, on a life now 45 years of age, interest 5 *per cent.*

Operation according to No. 186.

$$\begin{array}{rll}
v^{10} = & {\cdot}613913\ \lambda & \bar{1}{\cdot}7881068 \\
{}^{10}a = & 4073\ \lambda & 3{\cdot}6099144 \\
a = & 4727\ \varkappa & \bar{4}{\cdot}3254144 \\
{}_{10}av^{10} = & {\cdot}528976\ \lambda & \bar{1}{\cdot}7234356 \\
1+{}^{10}\text{A} = & 11{\cdot}347\ \lambda & 1{\cdot}0548811 \\
\text{Subtract} & 6{\cdot}002\ \lambda & 0{\cdot}7783167 \\
\text{from } 1+\text{A} = & 13{\cdot}648 & \\
\text{remains} & 7{\cdot}646\ \varkappa & \bar{1}{\cdot}1165657 \\
1-{}_{10}av^{10} = & {\cdot}471024\ \lambda & \bar{1}{\cdot}6730430 \\
 & {\cdot}061604\ \lambda & \bar{2}{\cdot}7896087 \\
v = & {\cdot}952381 &
\end{array}$$

$$\odot\,{}_{\overline{10|}}\mathfrak{A} = {\cdot}013985, \text{ agreeably to No. 96.}$$

What has been advanced from number 99 to 109 needs no algebraical illustration.

(J. M.)

ANNULAR, resembling a ring or circle.

ANNULAR CRYSTAL, in *Mineralogy*, is a hexahedral prism with six, or an octahedral prism with eight marginal faces disposed in a ring about the base; or these prisms truncated on all their terminal edges.

ANNULAR ECLIPSE, in *Astronomy*, is caused by the dark body of the moon intervening so as to obscure the whole of the sun's disc except a marginal ring of light.

ANNULARIA, Sternberg's designation for a fossil genus of plants of the coal formation, with leaves disposed in whorls.

ANNULET, a little circle, borne as a charge in coats of arms, as also added to them as a *difference*. Among the Romans it represented liberty and nobility. It also denotes strength and eternity, by reason of its endless form.

ANNULOSA (from *annulus*, a ring or segment), a term in zoology, applied by naturalists to a great division of the animal kingdom. It contains five classes, viz., CRUSTACEA, MYRIOPODA, ARACHNIDES, INSECTA, and VERMES.

ANNUNCIADA, ANNUNTIADA, or ANNUNCIATA, an order of knighthood in Savoy, instituted by Amadeus I., in the year 1049. Their collar was of 15 links, interwoven one with another in form of a true lover's knot; and the motto F. E. R. T., signifying *Fortitudo ejus Rhodum tenuit.* Amadeus VIII. gave the name *Annunciada* to this order, which was formerly known by that of *the knot of love;* changing at the same time the image of St Maurice, patron of Savoy, which hung at the collar, for that of the Virgin Mary; and, instead of the motto above mentioned, substituting the words of the angel's salutation.

ANNUNCIATION, the tidings brought by the angel Gabriel to the Virgin Mary of the incarnation of Christ. Annunciation is also a festival kept by the church on the 25th of March in commemoration of these tidings. This festival appears to be of very great antiquity. There is mention made of it in a sermon which goes under the name of Athanasius. Others carry it up to the time of Gregory Thaumaturgus, because there is a sermon likewise attributed to him upon the same subject. But the best critics reject both these writings as spurious. However, it is certain that this festival was observed before the time of the council of Trullo, in which there is a canon forbidding the celebration of all festivals in Lent excepting the Lord's Day and the Feast of the Annunciation; so that we may date its origin from the seventh century. In the Romish church, on this feast, the pope performs the ceremony of marrying or cloistering a certain number of maidens, who are presented to him in the church, clothed in white serge, and muffled up from head to foot. An officer stands by, with purses containing notes of 50 crowns for those who make choice of marriage, and notes of 100 for those who choose the veil.

ANNUNCIATION is likewise a title given by the Jews to a part of the ceremony of the Passover.

ANNUS DELIBERANDI, in *Scots Law*, the space of a year which is allowed an heir for deliberating whether he will enter on possession.

ANOA, a quadruped, seemingly of the antelope genus, the horns of which have lately been brought from Celebes; but it is otherwise unknown to naturalists.

ANODYNE (from α, negative, and ὀδύνη, *pain*), a term applied to medicines which ease pain and procure sleep.

ANOMALISTICAL YEAR, in *Astronomy*, the time that the earth takes to pass through her orbit: it is also called the *Periodical Year*. The space of time belonging to this year is greater than the tropical year, on account of the precession of the equinoxes.

ANOMALOUS (from α, priv., and νόμος a law), a term applied to whatever is irregular, or deviates from the rule observed by other things of the like nature.

ANOMŒANS, in *Ecclesiastical History*, the name by which the pure Arians were called in the fourth century, in contradistinction to the Semi-Arians. The word is derived from the Greek ἀνόμοιος, *different, dissimilar;* for the pure Arians asserted that the Son was of a nature different from, and in nothing like, that of the Father; whereas the Semi-Arians acknowledged a likeness of nature in the Son, at the same time that they denied, with the pure Arians, the consubstantiality of the Word. The Semi-Arians condemned the Anomœans in the council of Seleucia; and the Anomœans, in their turn, condemned the Semi-Arians in the councils of Constantinople and Antioch, erasing the word ὅμοιος, *like*, out of the formula of Rimini and that of Constantinople.

ANONYMOUS (α, priv., and ὄνομα), something that is nameless, or of which the name is concealed. It is a term applied to books and to contributions to journals and other periodical works published without the name of the author.

Anonymous writing is, no doubt, like the gifts of Providence, liable to abuse, especially when it is employed to slander private character, or to circulate unfair criticisms on literary subjects: against the first of these the courts of law are some protection, and a free press will counteract the other. It is, however, in the discussion of public measures that its influence is most important. While an individual might be deterred from openly exposing himself to the persecutions of authority, or the malevolence of arbitrary power, he is enabled, without danger, under the shelter of the impersonal character of the press, to denounce the dangerous or flagitious character of measures proposed by the government. But it is not only against the vengeance of governments and statesmen that anonymous writing is a protection It equally shields from the rage of vulgar and unscrupulous opponents the writers who attempt to dispel the illusions which from time to time are produced by the declamatory harangues and usurped ascendency of dangerous agitators; and it is doubtful if freedom could long be sustained in a country where anonymous writing is prohibited.

The law passed by the National Assembly of France during the days of the last republic, by which the writers in public journals were compelled to sign their articles, injuriously affected the independence and dignity of the press, and contributed in some measure to prepare the public mind for the subversion of free institutions. The *Dictionnaire des Anonymes et des Pseudonymes*, by Barbier, is a very valuable work, and throws much light on the history of many anonymous and pseudonymous publications.

ANOPLOTHERIUM, a fossil genus of pachyderm quadruped, discovered by Cuvier in the gypsum of the Paris basin. It had divided hoofs. The two species are *A. commune*, and *A. gracilis.*—See *Ossem. Fossil.* and *Buckland's Bridgewater Treatise.*

ANORTHITE, a crystallised mineral, a silicate of alumina and lime, found principally in the dolomite ejected from Vesuvius. The crystals are vitreous, white, and in doubly oblique prisms.

ANOSMIA (α, priv., and ὀσμή, *odor*), a deprivation of the olfactory sense: a singular affection, and fortunately of rare occurrence. Anosmia has sometimes occurred as a congenital defect; but it more generally has its origin in a diseased state of the *membrana mucosa* itself. The habituation of the olfactories to strong stimuli has been known to produce a similar effect.

ANOTTA, or ARNOTTO, in dyeing, a yellowish red colour, formed from the pellicles or pulp of the seeds of the *Bixa Orellana*, a tree common in South America. It is also called *Terra Orellana*, and *Roucou.*

The manner of making anotta is as follows:—The red seeds, cleared from the pods, are steeped in water for seven or eight days, or longer, till the liquor begins to ferment;

Anquetil. then strongly stirred, stamped with wooden paddles and beaters, to promote the separation of the red skins: this process is repeated several times, till the seeds are left white. The liquor, passed through close cane sieves, is pretty thick, of a deep red colour, and an offensive smell; in boiling, it throws up its colouring matter to the surface in form of scum, which is afterwards boiled down by itself to a due consistence, and made up while soft into balls. The anotta commonly met with among us is moderately hard and dry, of a brown colour on the outside, and a dull red within. It is not easily acted upon by water, and tinges the liquor only of a pale brownish yellow colour. It very readily dissolves in rectified spirit of wine, and communicates a high orange or yellowish red. Hence it is used as an ingredient in varnishes, for giving more or less of an orange cast to the simple yellows. Alkaline salts render it perfectly soluble in boiling water, without altering its colour. Wool or silk boiled in the solution acquires a deep, but not a very durable, orange dye. Its colour is not changed by alum or by acids, any more than by alkalies; but when imbibed in cloth, it is discharged by soap, and destroyed by exposure to the air. It is used to colour cheese.

ANQUETIL, Louis Pierre, a French historian, was born at Paris on the 21st of Jauuary 1723. At the age of 17 he entered the congregation of St Genevieve, where he taught theology and literature with ability and success. He afterwards became director of the academy at Rheims; and in 1759 he was appointed prior of the abbey de la Roe, in Anjou. Soon after this he was sent, in the capacity of director, to the college of Senlis. In 1766 he obtained the curacy or priory of Chateau-Renard, near Montargis, which he exchanged, at the commencement of the Revolution, for the curacy of La Villette, in the neighbourhood of Paris. During the reign of terror he was imprisoned at St Lazare. On the establishment of the National Institute, he was elected a member of the second class, and was soon afterwards employed in the office of the minister for foreign affairs. He died on the 6th of September 1808, in the 86th year of his age. On the evening previous to this event, he is reported to have said to one of his friends, "Come and see a man who is dying full of life."

As an author, M. Anquetil does not stand very high in the ranks of literature. He possessed more industry in research than ability or judgment in execution. His style is censurable in many respects, and he appears to have been almost entirely destitute of the critical discernment and philosophical sagacity which are requisite to form the character of a good historian. The following is a list of his principal works:—

1. *Histoire Civile et Politique de la Ville de Reims.* 1756–57, 3 vols. 12mo. The history is brought no farther down than 1657: a fourth volume should have been added, but it never appeared. Anquetil is said to have written this work in concert with one Felix de la Salle, and it is, perhaps, the best of all his productions. 2. *Almanach de Reims.* 1754, 24mo. 3. *L'Esprit de la Ligue, ou Histoire Politique des Troubles de France pendant les 16 et 17 siècles.* 1767, 3 vols. 12mo. This work has been frequently reprinted. 4. *Intrigue du Cabinet sous Henri IV. et sous Louis XIII. terminée par la Fronde.* 1780, 4 vols. 12mo. 5. *Louis XIV. sa Cour et le Régent.* 1789, 4 vols. 12mo; reprinted in 1794, 5 vols. 12mo. 6. *Vie du Maréchal de Villars, écrite par lui-même, suivie du Journal de la Cour de 1724 à 1734.* Paris, 1787, 4 vols. 12mo; reprinted in 1792. 7. *Précis de l'Histoire Universelle.* 1797, 9 vols. 12mo; reprinted in 1801 and 1807, in 12 vols. 12mo. This work has been translated into English, Spanish, and Italian. 8. *Motifs des Guerres et des Traités de Paix de la France. pendant les règnes de Louis XIV., Louis XV., et Louis XVI.* 1798, 8vo. 9. *Histoire de France depuis les Gaules jusqu'à la fin de la Monarchie.* 1805 et *seqq.* 14 vols. 12mo. This work was composed in haste, and is of no great value. 10. *Notice sur la Vie de M. Anquetil du Perron.* M. Anquetil likewise wrote several papers in the Memoirs of the Institute. (See *Biographie Universelle.*) (J. C.)

Anquetil du Perron. Anquetil du Perron (*Abraham Hyacinthe*), brother of the subject of the preceding article, was born at Paris on the 7th of December 1731. Having distinguished himself as a student at the university of that city, and acquired a considerable knowledge of the Hebrew language, he was invited to Auxerre by M. de Caylus, then the bishop of that diocese. This prelate made him study theology, first at the academy of his diocese, and afterwards at that of Amersfort, near Utrecht; but Anquetil had no desire to embrace the ecclesiastical vocation, and devoted himself with ardour to the study of the different dialects of the Hebrew, and of the Arabic and Persian. Neither the solicitations of M. de Caylus, nor the hopes of rapid preferment, had the power to detain him at Amersfort after he thought he had acquired everything that was to be learnt there. He returned to Paris, where his diligent attendance at the Royal Library, and his ardour in the prosecution of his favourite studies, attracted the attention of the Abbé Sallier, keeper of the manuscripts, who introduced him to the acquaintance of his associates and friends, whose united exertions procured for him a small salary, as student of the oriental languages. He had scarcely received this appointment, when, having accidentally laid his hands on some manuscripts in the *Zend*, he formed the project of a voyage to India, with the view of discovering the works of Zoroaster. At this period an expedition was preparing at the port of L'Orient, which was destined for India. M. du Perron, however, applied in vain, through his protectors, for a passage; and seeing no other means of accomplishing his plan, he enlisted as a common soldier, and set out from Paris, with a knapsack on his back, on the 7th of November 1754. His friends procured his discharge; and the minister, affected by his romantic zeal for science, granted him a free passage, a seat at the captain's table, and a salary, the amount of which was to be fixed by the governor of the French settlements in India. After a passage of nine mouths, Anquetil landed, on the 10th of August 1755, at Pondicherry. Here he remained no longer than was necessary to make himself master of the modern Persian, and then hastened to Chandernagore, where he thought to acquire the Sanscrit. But in this he was deceived; and he was on the point of returning, when a serious complaint threatened his life. He had scarcely escaped from this danger, when war was declared between France and England; Chandernagore was taken; and Anquetil resolved to return to Pondicherry by land. After a journey of one hundred days, in the course of which he encountered many adventures, and suffered many hardships, he arrived at Pondicherry. Here he found one of his brothers who had arrived from France, and embarked with him for Surat; but, with the view of exploring the country, he landed at Mahe, and proceeded on foot. It was at Surat that he succeeded, by perseverance and address in his intercourse with the native priests, in acquiring a sufficient knowledge of the languages to enable him to translate the Dictionary called the *Vedidad-Sade*, and some other works. From thence he proposed going to Benares, to study the languages, antiquities, and sacred laws of the Hindus; but the capture of Pondicherry obliged him to return to France. He accordingly embarked on board an English vessel, and landed at Portsmouth in the month of November 1761. After spending some time in London, and visiting Oxford, he set out for Paris, where he arrived on the 4th of May 1762, without fortune or the desire of acquiring any, but esteeming himself rich in the possession

of one hundred and eighty oriental manuscripts, besides other curiosities. The Abbé Barthelemy, and his other friends, procured for him a pension, with the title and appointments of Interpreter of the oriental languages at the royal library. In 1763 the Academy of the *Belles Lettres* received him among the number of its associates; and from that period he devoted himself to the arrangement and publication of the materials he had collected during his eastern travels. In 1771 he published a work in three volumes 4to, under the title of *Zend-Avesta*, containing collections from the sacred writings of the Persians, among which are fragments of works ascribed to Zoroaster; and he accompanied this work with an account of the life of that sage. This publication must be considered as constituting a very important accession to our stores of oriental literature. A recent historian, and very competent judge, refers to the *Zend-Avesta*, as certainly the most authentic source from which we can derive information regarding the religion and institutions of the great Persian legislator. (Sir John Malcolm's *Hist. of Persia*, vol. i. p. 193, note. To the *Zend-Avesta* M. du Perron prefixed a discourse, in which he treated the university of Oxford, and some of its learned members, with ridicule and disrespect. Mr (afterwards Sir William) Jones replied to these invectives in an anonymous letter, addressed to the author, written in French, with uncommon force and correctness of style, but at the same time with a degree of asperity which could only be justified by the petulance of M. du Perron. In 1778 he published his *Législation Orientale*, in 4to, a work in which he controverts the system of Montesquieu, and endeavours to prove that the nature of oriental despotism has been misrepresented by most authors: that in the empires of Turkey, Persia, and Hindustan, there are codes of written law which equally bind the prince and subject; and that in these three empires the inhabitants possess both movable and immovable property, which they enjoy with perfect security. His *Recherches Historiques et Géographiques sur l'Inde* appeared in 1786, and formed part of Thieffenthaler's *Geography of India*. They were followed in 1789 by his treatise *De la Dignité du Commerce et de l'Etat du Commerçant*. The Revolution seems to have greatly affected him. During that period he abandoned society, shut himself up in his study, and devoted himself entirely to literary seclusion. In 1798 he published *L'Inde en Rapport avec l'Europe*, &c. in 2 vols. 8vo; a work which is more remarkable for its virulent invectives against the English, and for its numerous misrepresentations, than for the information which it conveys, or the soundness of the reflections which it contains. In 1804 he published a Latin translation from the Persian of the *Oupnek'hat* or *Upanischada, i. e.*, Secrets which must not be revealed, in 2 vols. 4to. On the re-organisation of the Institute, M. Anquetil was elected a member, but soon afterwards gave in his resignation. He died at Paris on the 17th of January 1805.

Besides the works we have already enumerated, M. Anquetil read to the academy several memoirs on subjects connected with the history and antiquities of the East. At the time of his death he was engaged in revising a translation of the *Travels of Father Paulin de St Barthelemy in India*, which work was continued by M. Silvestre de Sacy, and published in 1808, in 3 vols. 8vo. He also left behind him a great number of manuscripts, among which his biographers particularly notice the translation of a Latin treatise *on the Church*, by Doctor Legros, in 4 vols. 4to. See *Biographie Universelle; Monthly Review*, vol. 61; Lord Teignmouth's *Life of Sir William Jones*. (J. C.)

ANSÆ, in *Astronomy*, implies the parts of Saturn's ring projecting beyond the disc of the planet. The word is Latin, and properly signifies *handles;* these parts of the ring appearing like handles to the body of the planet.

ANSARIANS, a people of Syria, also called *Ensarians*, properly *Nassaris* and *Ansayri*. The territory occupied by the Ansarians is that chain of mountains which extends from Antakia to the rivulet called *Nahr-el-Kabir*, or the Great River. They are divided into several tribes or sects, among which are distinguished the Shamsia, or adorers of the sun; the Kelbia, or worshippers of the dog; and the Kadmousia, who are said to pay a particular homage to that part in women which corresponds to the priapus. This last tribe appears from Colonel Chesney's account, to be the same as the *Ismaïli*, who implicitly obey their chief Sheikh-al-Hashishin. They are the tribe of *Assassins*, whose principal seat is in the mountains of Persia.—*Expedition to Euphrates and Tigris*, vol. i. p. 543. Their name is now believed to be derived from the narcotic hemp, *Cannabis indica*, which is called in Persia *haschis-sin*, and is employed to intoxicate. The Ansarians have strongholds in the mountains of Tripoli; but their chief seat is in Persia. They are a more vigorous race than most Orientals; browner than the Turks, but fairer than the Arabs. It is said they can muster 40,000 fighting men.

ANSBACH, or ANSPACH, a fortified city of Bavaria, the capital of the circle of Middle Franconia, and of the bailiwick of the same name. It stands on the river Rezat, twenty-five miles south-west of Nuremberg, and in 1846 contained 12,254 inhabitants. It has a royal castle, once the residence of the Margraves of Anspach; a gymnasium, hospital, orphan-asylum, public library, &c., and manufactures of woollen and cotton stuffs, earthenware, tobacco, cutlery, playing-cards, &c.

ANSE, an ancient town of France, in the Lyonnois, on the river Saone. It is the capital of a canton in the department of the Rhone, and formerly bore the title of barony. Pop. 1750. 13½ miles north of Lyons. Long. 4. 44. E. Lat. 45. 55. N.

ANSELM, St, archbishop of Canterbury, in the reigns of William Rufus and Henry I. He was born in the year 1033, at Aosta, a town in Piedmont, at the foot of the Alps. He became a monk in the abbey of Bec in Normandy, of which he was afterwards chosen prior, and then abbot. In the year 1092 he was invited over to England by Hugh earl of Chester; and in the year following was prevailed on to accept the archbishopric of Canterbury. He enjoined celibacy on the clergy, for which he was banished by King Rufus; but recalled by Henry on his coming to the crown. In conformity to Pope Urban's decree, he refused to consecrate such bishops as were invested by the king, denying it to be the royal prerogative: for this he was banished again, till, the pope and king agreeing, he was recalled in 1107. In short, from the day of his consecration to that of his death, he was continually employed in extending the encroachments of the church against the prerogative of the crown; and for that purpose spent much of his time in travelling between England and Rome, for the advice and direction of his Holiness. He may be regarded as having been, besides A'Becket, the only English prelate who strenuously pursued in his ecclesiastical relations that policy distinguished as *ultramontane*. At the council of Bari, in the kingdom of Naples, the pope being puzzled by the arguments of the Greeks against the Holy Ghost's proceeding from the Father, called upon Anselm to answer their objections, which he did with great success. He wrought many miracles, if we may believe the author of his life, both before and after his death, which happened at Canterbury in the 76th year of his age, A.D. 1109, and was canonized in the reign of Henry VII. "His death was that of a saint and a philosopher; his ardour for science glowed upon his death-bed. His disciples were around him weeping and praying; the last holy rites had already enveloped him in the atmosphere of eternity; infi-

nite truths were now to be unfolded to him in clear vision; when at this last moment he cast his thoughts over the obscurities of earthly science, and recalling the efforts he had made to render them more clear, said to his disciples, 'I could have wished before my death to have put down in writing my ideas upon the origin of evil, for I had got some explanations which will now be lost.' A few moments after he passed to where all problems are solved."

Anselm deserves to be remembered as one of the principal revivers of literature, after three centuries of profound ignorance. In a philosophical relation, he may be regarded as the founder of the scholastic metaphysics, and his ontological argument for the existence of Deity entitles him to be considered as one of the acutest of natural theologians. His speculations on that subject are contained in his two treatises entitled *Monologium* and *Proslogium*, composed while he was prior of the Abbey of Bec. The arguments used in the first of these are to be found in the writings of previous philosophers, though not so fully and rigorously developed as is done by Anselm. But the argument contained in the *Proslogium*, originally suggested by St Augustine, and afterwards known as the *Cartesian argument*, is that on which the peculiar fame of Anselm as a metaphysician is founded. It may be briefly expressed thus,—*The human mind possesses the idea of a Being than whom it can conceive none other higher. This perfect Being is in virtue of that very perfection conceived as really existent. Therefore he does so exist.* Anselm sought a general principle for the foundation of all science, a principle such as should unite *logical* and *real* universality, *i. e.*, at once comprehend all other ideas and express a reality conceived as the source of all other realities. This principle he found in the idea of God—of infinite perfection. To deny to this idea a corresponding reality involves a contradiction, for then there must be a higher perfection conceivable, viz., this absolute perfection not merely as possible but as existing, since it is more perfect to exist than to be merely possible. Here Anselm found the principle he was in search of, this idea of God involving both logical and real universality, since on the one hand all other ideas are contained under this, as the lesser is contained in the greater; and on the other, it constitutes the necessary source of all finite existences.

This argument of Anselm seems not to have been generally admitted during the middle ages, and was decisively rejected by such men as Aquinas. It was replied to in his own time by a monk named Gaunilon, in a treatise entitled *Liber pro insipiente adversus Anselmi in Proslogio ratiocinationem*, which contains implicitly all the objections subsequently raised against it as developed by Descartes; the principal and fatal objection being the logical incompetency of deducing the reality of existence from the necessity of thought, of passing from the finite ideas of the human mind to the infinite reality of a Divine existence.

The works of Anslem have been often reprinted. The best edition is that of Father Gerberon, printed at Paris in 1675, in two vols. folio.

ANSELM *of Laon*, a famous theologian, who taught at Paris with great success about the year 1076. With the assistance of his brother Ralph de Laon, he established in his native place a school of philosophy, which became famous throughout Europe. Anselm died in 1117. His interlinear gloss on the Scriptures has frequently been printed.

ANSON, GEORGE, *Lord*, the famous circumnavigator, was the second son of William Anson, Esq. of Shuckborough Manor, Staffordshire, where he was born on the 23d April 1697. Showing an early inclination for the sea, he received a suitable education. The first command he enjoyed was that of the Weasel sloop in 1722; but the most memorable action of his life, and the foundation of his future good fortune, took place on his receiving the command of five ships, a sloop, and two victuallers, equipped to annoy the Spaniards in the South Seas, and to co-operate with Admiral Vernon across the Isthmus of Darien; an expedition the principal object of which failed by the unaccountable delay in the fitting out. He sailed, however, in September 1740; doubled Cape Horn in a dangerous season; lost most of his men by the scurvy; and with only one remaining ship, the Centurion, crossed the Great Pacific Ocean. If no considerable national advantage resulted from this voyage, Commodore Anson made his own fortune, and enriched his surviving companions, by the capture of a rich galleon on her passage from Acapulco to Manilla, with which he returned home round the Cape of Good Hope. If he was lucky in meeting this galleon, he was no less fortunate in escaping a French fleet then cruising in the Channel, by sailing through it during a fog. He arrived at Spithead in June 1744. In a short time after his return he was appointed rear-admiral of the blue, and one of the lords of the admiralty. In April 1745 he was made rear-admiral of the white, and the following year vice-admiral of the blue, at which time he was chosen to represent the borough of Heydon in parliament. In 1747, being on board the Prince George of 90 guns, in company with Admiral Warren and 12 other ships, he intercepted, off Cape Finisterre, a powerful fleet, bound from France to the East and West Indies; when, by his valour and conduct, he again enriched himself and his officers, and at the same time strengthened the British navy, by taking six men of war and four East Indiamen, not one of them escaping. The French admiral, M. Jonquiere, on presenting his sword to the conqueror, said, *Monsieur, vous avez vaincu l'Invincible, et la Gloire vous suit*—"Sir, you have conquered the Invincible, and Glory follows you;" pointing to the ships named the *Invincible* and the *Glory*, which he had taken. For his signal services he was created baron of Soberton in Hants. The same year he was appointed vice-admiral of the red; and, on the death of Sir John Norris, was made vice-admiral of England. In 1748 he was made admiral of the blue: he was afterwards appointed first lord of the admiralty, and was at length made admiral and commander-in-chief of His Majesty's fleet, in which rank he continued, with a very short interval, until his death; and the last service he performed was to convey Queen Charlotte to England. He died in June 1762. No performance ever met with a more favourable reception than the account of Anson's voyage round the world. Though it is printed under the name of his chaplain, it was composed under his lordship's own inspection, and from the materials he himself furnished, by Mr Benjamin Robins.

ANSTEY, CHRISTOPHER, a comic writer, who published in 1766 *The New Bath Guide*, a satirical poem, abounding in coarse humour, and which obtained a degree of popularity almost unparalleled at that period; so much so, indeed, that Dodsley the bookseller, with a liberality scarcely less remarkable, presented the copyright again to the author, in consideration of the profit he had realized by its sale. Anstey was the son of the Rev. C. Anstey, D.D. of Brinkley, and was educated at King's College, Cambridge, where, as a fellow, he continued to reside till the year 1754. Succeeding to some family estates at Trumpington, he made that place his home, and soon afterwards married. He died in 1805, aged eighty-one. His several poems were collected and published in 1808, in 1 vol. 8vo. He was honoured with a cenotaph in "Poet's Corner," in Westminster Abbey, a distinction which has been conferred in more instances than this with too little discrimination.

ANSTRUTHER, EASTER, a royal burgh and parish of Scotland, in the county of Fife, on the north shore of the

Firth of Forth. It possesses an excellent harbour. Population of burgh in 1851, 1161. Ten miles south of St Andrews. Dr Chalmers was a native of this place.

ANSTRUTHER, *Wester*, a parish and small seaport of Scotland, situated close to Easter Anstruther, with which, and the towns of St Andrews, Cupar, Crail, Pittenweem, and Kilrenny, it unites in returning a member to parliament. The parish includes the Isle of May. Population of burgh in 1851, 365. Long. 2. 44. W. Lat. 56. 14. N.

ANT. The history of a tribe of insects so long celebrated for their industry and frugality, and for the display of that sagacity which characterizes some of the higher orders of animals, is peculiarly calculated to occupy the attention of modern naturalists. The ancients, indeed, had often noticed the habits and economy of the ant; but their accounts, at all times deficient in accuracy from the want of precise definitions and logical arrangement of the objects they describe, are in this instance so mixed up with fanciful notions and chimerical doctrines, and so coloured by the vivid imagination and credulity of the narrators, as to have retarded rather than advanced the progress of real knowledge. Aristotle and Pliny report, for instance, that the labours of ants are in a great measure regulated by the phases of the moon; and the latter mentions a species found in the northern parts of India, whose size was said to equal that of the wolves of Egypt, whose colour was the same as that of a cat, and whose occupation in winter consisted in digging up gold from the bowels of the earth; while the inhabitants in the summer robbed them of their treasures, after having decoyed them, by stratagem, from their nests. Great mistakes have prevailed, even in later times, from the circumstance of the larvæ of ants bearing a resemblance to grains of corn, which it was supposed these insects hoarded up as a provision for winter consumption. The form of the eggs and of the larvæ, and the attention paid to them by the ants, were described by Dr King in the 23d number of the *Philosophical Transactions;* but Leeuwenhoeck was the first who distinguished with precision the different forms which the insect assumes in the several stages of its growth. He traced the successive changes from the egg to the larva, the nymph, and the perfect insect. Swammerdam pursued his scrutiny into these successive developments with greater minuteness; and, unrivalled in the art of microscopic dissection, discovered the wonderful encasement of all the parts of the future ant at every preceding stage, and showed that it appears under such different forms only from the nature of its envelopes, each of which, at the proper period, is in its turn cast off. Linnæus (*Memoirs of the Royal Academy of Sciences at Stockholm*, vol. ii.) ascertained some of the leading facts with regard to the distinction between the sexes, and determined that the ants which are furnished with wings are the only individuals that exercise the sexual functions. Several particulars with regard to the economy of the ants were published by Mr Gould, in a book entitled *An Account of English Ants*, of which an abstract is given in the *Philosophical Transactions* for 1747, by the Rev. Dr Miles. The facts are there stated with tolerable correctness; but some errors have been committed by following too closely the analogy with bees. Geoffroy (*Histoire des Insectes qui se trouvent aux Environs de Paris*), though a good naturalist on other topics, is a bad authority on the subject of ants. The most complete series of observations on the natural history of these insects, is that for which we are indebted to the celebrated Swedish entomologist De Geer (*Mémoires pour servir à l'Histoire des Insectes*), an observer on whose fidelity the most implicit reliance may be placed.

In the *Encyclopédie Méthodique*, under the article *Fourmi*, Olivier has drawn up an able statement of all the material facts that had been established by preceding naturalists; without, however, adding any original observations of his own, excepting the description of five or six undescribed species. A full account of the habits of those ants which for a long period infested the island of Martinique, is contained in some of the earlier numbers of the *Journal de Physique* (vols. ix. and x.) The author of these memoirs, M. Barboteau, has given many curious details on this subject, and has cited a number of facts on various authorities; and the account might now be swelled by the reports of subsequent travellers in different parts of the world; but these statements are often made upon slender authority, and are too much tinctured with the marvellous to admit of much credit being attached to them. The narrative given to us by Bonnet in the second volume of his *Observations sur les Insectes*, of the proceedings of a colony of ants which had established itself in the head of a large thistle, and which he transported into his house, is highly interesting; but it elucidates only a few points of their economy, and leaves us to regret that so patient and indefatigable an observer had not bestowed more of his attention to the study of this tribe of insects. In the *Philosophical Transactions* for 1790 we find an interesting memoir on the sugar-ant, a species which, for a period of ten years, committed dreadful ravages in the sugar plantations throughout the whole island of Grenada. The most methodical account of this tribe of insects that has yet appeared is that of Latreille, in his *Histoire Naturelle des Fourmis*, published at Paris in 1802, a work which alone would have secured the reputation of the author as an able and scientific naturalist. His merit is particularly conspicuous in the clearness and accuracy of his descriptions of each species, and the luminous method of arrangement which he has adopted in their classification. He gives an account of one hundred species which he had himself observed, and of twenty-four which he has described from the reports of others: these he distributes into nine natural families, according to the situation and structure of the antennæ, and the form of the abdominal scales. But the work which contains the most copious collection of facts relative to the habits and economy of ants is that of Mr P. Huber of Geneva, entitled *Traité des Mœurs des Fourmis Indigènes*, published in 1810. By means of an apparatus which he contrived so as to admit of his obtaining a view whenever he pleased of the inmost recesses of their habitation, he was enabled to observe what was going on in the interior of the nest, and to investigate with success some of the most important and interesting features of their history. The results of his researches, as they are reported in his work, are highly curious and instructive, and open a wide field of speculation and inquiry to the philosophical entomologist. They have not only elucidated many obscure points with regard to one tribe of insects, but have disclosed some general views of the instincts and faculties of this order of the creation, which are totally new, and must tend, in a considerable degree, to exalt our conceptions of the inexhaustible powers and resources of nature.

Economy and policy of ants.

Having thus pointed out the principal sources of information in this department of entomology, we shall proceed to give an outline of the leading facts that have been ascertained relative to the economy and domestic policy of these remarkable insects.

Functions of the neuters.

In common with many tribes of hymenopterous insects, ants present the remarkable peculiarity of a threefold distinction of sex among the individuals of the same species; a circumstance which is met with in no other order of the animal kingdom, and which appears, as far as observation has extended, to be totallv excluded from the plan

of the vegetable creation. Besides males and females, there exists an apparently intermediate order of *neuters*, which are also denominated labouring or working ants. The neuters, thus exempted from every sexual function, exercise, on the other hand, all the other offices necessary for the existence and welfare of the community to which they belong. It is they who collect supplies of food, who explore the country for this purpose, and seize upon every animal substance, whether living or dead, which they can lay hold of, and transport to their nest. It is they who construct every part of their dwelling-place, who attend to the hatching of the eggs, to the feeding of the larvæ, and to their removal, as occasion may require, to different situations favourable to their growth and development; and who, both as aggressors and as defenders, fight all the battles of the commonwealth, and provide for the safety of their weaker and more passive companions. Thus all the laborious and perilous duties of the state are performed solely by this description of ants, who act the part of helots in these singularly constituted republics of insects. We find, however, on closer examination, that, in all probability, this anomaly in point of sex is more apparent than real; and that, however different in external conformation from the productive females, they nevertheless originally and essentially belong to the same sex. There is every reason to believe that the development of the sexual organs in the former is the consequence of some difference in the circumstances in which the larva is placed during its growth. That such is the case with bees, is now perfectly well established; and the analogy of bees with ants, in many points of physiology, must be admitted as a strong argument in corroboration of this theory. In all the essential features of internal structure, the supposed neuters agree with the female, and differ from the male of the same species. In all hymenopterous insects, which are armed with stings, a difference exists in the two sexes, as to the number of articulations composing the antennæ; those of the female consisting of fewer pieces than those of the male. The accurate observations of Mr Kirby (*Monographia Apum*) have determined that in the bee the antennæ of the male have fifteen articulations, while those of the female and the neuter have only fourteen. In the ant, likewise, we find thirteen articulations in the male, and only twelve in the female; and likewise only twelve in the neuter. In the male ant the abdomen has seven rings, in the female and neuter only six. In the two latter classes the head is broader, and the mandibles very large and powerful compared with those of the male, and are furnished with serrated edges, and a sharp and often hooked point. The external sexual organs of the female and of the neuter are so nearly similar in appearance, that Latreille declares he was unable to perceive the least difference between them. On the other hand, it is to be observed, that in the neuter the principal deviation from the model of the female consists in the absence of wings; a circumstance which, as it regards the organs of locomotion only, is one of subordinate importance in the economy; and their presence may, without difficulty, be conceived to be connected with a certain condition of the sexual organs, as are the horns of the deer, and the beard in the human species. But although of so little consequence in a physiological point of view, it is a circumstance materially affecting their external condition. It dooms them to severe toil and exertion in traversing the ground, and in climbing up the steep paths that may lie in their route; while their more luxurious and favoured associates are fluttering in the spacious realms of air in search of amusement, and wafted to the objects of their gratification on the light breezes of the summer.

Sensitive powers of ants.

Ants appear to be endowed with a greater share of muscular strength than almost any other insect of the same size. Of this we have sufficient proofs in the vivacity of their movements, the incessant toil which many undergo, the great loads which they are seen to carry, often exceeding ten or twelve times their own weight, and the agility which they exert in making their escape from danger. This high degree of irritability is conjoined, apparently, with a corresponding share of the power of sensation; a power which is manifested in their susceptibility to a variety of impressions capable of affecting the organs of sense. They have a quick perception of all changes of temperature, as well as of other conditions of the atmosphere; and are readily and disagreeably affected by moisture. In the perfection of the sense of sight they seem to be nearly on a level with other insects; and the males and females are provided with both the descriptions of eyes peculiar to this class, namely, the composite and the simple eyes. The labouring ants, indeed, who never fly, are frequently destitute of the latter kind; a circumstance which appears to confirm the suspicion that has often been entertained, that the simple eyes are chiefly instrumental in the vision of distant objects. Latreille describes two species of ants, in which he could not discover the least appearance whatsoever of eyes, although he employed a high magnifying power in examining them. One of these (the *Formica cæca*) is a foreign species, inhabiting the forests of Guiana, and of which the history is therefore little known. The other (the *Formica contracta*) is met with in the vicinity of Paris. It always conceals itself during the day under stones, or in obscure recesses, where no light can penetrate; and emerges from its retreat only during the night. It is much less social in its habits than other ants, collecting in groups only of about a dozen individuals, and appears to be far inferior in sagacity to the rest of the tribe.

Ants possess a considerable acuteness of smell, a sense which appears to be useful not only in directing them to their food, but also, as Bonnet first remarked, in enabling them to follow by the scent the track of their companions. If the end of the finger be passed two or three times across the line of their march, so as to brush off the odorous particles with which the ants who had already passed that way may have impregnated the track, those who follow immediately stop on arriving at the place where the experiment has been made, and afterwards direct their course irregularly, till they have passed over the space touched by the finger, when they soon find the path, and proceed with the same confidence as before. Bonnet repeated this experiment frequently, and always with the same result. Latreille has endeavoured to discover the seat of smell, which had long been suspected to reside in the antennæ. He, with this view, deprived several labouring ants of these organs, and replaced them near their nests. When thus mutilated, they wandered to and fro in all directions, as if they were delirious, and utterly unconscious of where they were going. Some of their companions were seen to notice their distress, and, approaching them with apparent compassion, applied their tongues to the bleeding wounds of the sufferers, and anointed them with a liquor which they caused to flow from their own mouths. This trait of sensibility was repeatedly witnessed by Latreille, while he was observing their actions with a magnifying lens.

It is indeed evident that, in all insects, the antennæ are organs of the greatest utility in conveying impressions from external objects. But in the ant, independently of their importance as organs of touch, they appear to be of still greater consequence to the welfare of the individual, and of the community to which it belongs, by being the

chief instruments which enable them to communicate to one another intelligence in which they are mutually interested, and on which they are called upon immediately to act. Mr Huber, to whom we are indebted for a variety of curious observations on this subject, has given the name of *Langage. Antennal* to this species of intercourse. The situation of the antennæ, which are placed in front of the head, their great mobility, their peculiar mechanism, which presents a series of phalanges having great freedom of play, and endowed with exquisite sensibility, conspire to fit them admirably for the function which he assigns to them,—that of producing a variety of different impressions, when applied in different ways to the antennæ or other parts of those ants with which they come in contact. Thus the signal of danger, which consists in the ant which gives the alarm striking its head against the corslet of the other, is propagated from ant to ant with astonishing quickness, throughout the whole society. For a few minutes a general ferment prevails, as if they were deliberating what measures to pursue; but their resolution is soon formed, and they are ready to rush in a body against the enemy. Any small animal that is discovered to have insolently invaded their repose is certain of falling a victim to their resentment, unless he can make a precipitate retreat, which he seldom effects without being covered with the bites of these furious insects. They are not, however, equally jealous of the intrusion of every kind of insect, for woodlice are often found in the interior of the nest, to whom, according to Latreille, they offer no molestation. Ants appear to be incapable of emitting sounds, so as to communicate with one another at a distance; and there is, indeed, no evidence that they possess the sense of hearing. The consideration of the sense of taste naturally comprehends that of their food, to which we shall therefore next proceed.

Their food, and depredations.

Very erroneous opinions were prevalent with regard to the food of ants, which have often been supposed to consume corn, and to do great injury to plants by devouring their roots or stems. The truth is, that they are chiefly carnivorous insects, preying indiscriminately on all the softer parts of animals, and especially the viscera of other insects. These, indeed, they will often attack when alive, and overpower by dint of numbers; either devouring their victim on the spot, or dragging it a prisoner into the interior of the nest. If, however, the game should be too bulky to be easily transported, they make a plentiful meal, and exert, like the bee, a power of disgorging a portion, and of imparting it to their companions at home: and it appears that they are even able to retain at pleasure the nutricious juices unchanged for a considerable time. The rapidity with which they consume, and in fact anatomize, the carcass of any small bird or quadruped that happens to fall in their way, is well known, and furnishes an easy method of obtaining natural skeletons of these animals, by placing their dead bodies in the vicinity of a populous ant-hill. In hot climates, where they multiply to an amazing extent, their voracity and boldness increase with their numbers. Bosman, in his description of Guinea, states that, in one night, they will devour a sheep, leaving it a fine skeleton; while a fowl is for them only the amusement of an hour. In these situations they will venture to attack even living animals of considerable size. Rats and mice often become their victims. The sugar-ants of Grenada cleared every plantation which they visited of rats and other vermin, which they probably effected by attacking their young. Poultry, or other small stock, could not be raised without the greatest difficulty; and the eyes, nose, and other emunctories of the bodies of dying or dead animals, were instantly covered with them. They generally, indeed, begin their attacks on the most sensible parts, which have the finest cuticle; and, accumulating in great numbers about the nostrils, destroy the animal by interrupting respiration. Negroes with sores had difficulty in keeping the ants from assailing them. Their power of destruction keeping pace with their increase of numbers, it is hardly possible to assign limits to either; and the united hosts of this diminutive insect have often become formidable to man himself. A story is related by Prévost, in his *Histoire Générale des Voyages*, of an Italian missionary, resident in Congo, who was awaked by his negroes in great alarm at the house being invaded by an immense army of ants, which poured in like a torrent, and before he could rise had already mounted upon his legs. They covered the floor and passages, forming a stratum of considerable depth. Nothing but fire was capable of arresting their progress. He states that cows have been known to be devoured in their stalls by these daring devastators. Smith, in his *Voyages to Guinea*, reports that at Cape Corse the castle was attacked by legions of ants, who were preceded by thirty or forty, apparently acting as guides. It was at day-break when they made this incursion, entering first by a chapel, on the floor of which some negro servants were lying. Assailed by this new enemy, they fled with precipitation, and gave the alarm to their master, who, on awaking, could hardly recover from his astonishment at beholding the advancing multitude, which extended for a quarter of a mile before him. There was not much time for deliberation; and a happy expedient was adopted of putting a long train of gunpowder across the line of their march, and extending it to their flanks, which had already begun to deploy, and, setting fire to the whole, millions were destroyed at one blow; which so intimidated the rest, that the whole army retreated in disorder, and did not renew the attack.

Descriptions of ant-hills of immense size abound in books of travellers who have visited tropical regions. Mr Campbell (*Account of Travels in South Africa*, published in 1815) observed in the district of Albany, at the Cape, an ant-hill, five feet high, and twelve in circumference. In the forests of Guiana, according to M. Malouet, they attain the height of from fifteen to twenty feet; and, when viewed from a distance on these widely extended savannas, resemble the rude huts of savages; but they contain a race more ferocious than the savage or the tiger himself, and cannot be approached by men without the utmost danger of being devoured. When new settlers, who are clearing the country, meet with any of these in their progress, they must immediately desist from their task, and even abandon the neighbourhood, unless they can speedily destroy the enemy in the very heart of the citadel which protects him, and from which he is able to pour an overwhelming number of combatants. The only method of accomplishing this is to dig a trench all round the ant-hills, and, after having filled it with dry wood and set fire to it on every side, by lighting it quickly in different places, so as to cut off all retreat to the ants, to batter down the edifice with cannon. The ants, thus scattered, soon perish in the flames.

The chief, if not the only vegetable substance which is at all alluring to their appetite, is *sugar*. They not only eat it in substance, but are fond of all fluids that contain it in any quantity,—such as the secretions which exude from many trees, and compose what has been termed the honey-dew; and the saccharine juice which is excreted from the bodies of many of the insects belonging to the genus Aphis. This latter species of food they appear to relish above all others: it resembles honey in its qualities, and is sucked with avidity from the insect which yields it, and which appears in no respect to suffer from the operation. Boissier de Sauvages was the first who noticed this

Ant.

singular fact; and Mr P. Huber has ascertained a number of curious circumstances attending it. He conceives that the liquor is given out voluntarily by the aphis, at the solicitation of the ant, who for this purpose strikes it gently and repeatedly with its antennæ, using the same motions as it does when caressing its young; and remarks, that the aphis retains this liquor for a longer time, where the ants are not at hand to receive it. A single aphis may often be seen surrounded by three or four ants who are feeding on the honey, and deriving from it a plentiful meal. It does not appear that the aphis uses any exertion to avoid the ants, who are thus dependent on its bounty; for those provided with wings are quite as passive under these circumstances as the rest. They are, however, of an extremely sluggish nature, and may be seen for days on the same stem, in a state of indolent repose, and averse to use their wings.

A singular observation has been recently made by Professor Savi (the younger) of Pisa, in relation to a species of Italian ant, the nest of which is inhabited by a small grasshopper. These animals do not appear to dwell in the same excavations in a merely casual manner, but they are united by some unaccountable bond of union, which renders the society of the one indispensable to the comfort of the other. The association of the ant and the aphis before alluded to is of a dissimilar nature, being the result of force on the one hand, and of necessity on the other. But, as far as it is possible to judge from the observations hitherto recorded, the cohabitation of the ant and the grasshopper is of a more refined and disinterested kind. It is really impossible at present to account for it on any other principle than that of an affectionate interest in each other's society; for no direct advantage appears to result to either party. On this account Signor Savi has named the grasshopper *gryllus myrmecophilus*.[1] He proved the friendly alliance which subsists between these species, by watching the migratory and other movements of the ants themselves, during which he discovered that they always carried their little grasshoppers along with them. These latter, during fine weather, are seen to sport and play in the vicinity of the ant-nests, into which they immediately betake themselves during any unfavourable change of the air, or the approach of threatened danger.

The cultivation of the sugar-cane in the West Indian islands has often been severely checked by the ravages of ants; but the injury they occasion arises altogether from their undermining the roots, in order to establish their nests where they can be protected from heavy rains, and secured against agitation from violent winds; advantages which the sugar-cane affords them in a very great degree. No part of the plant constitutes their food; and the same is true of those trees among the roots of which they burrow, and of which they speedily occasion the destruction, by preventing the access of moisture.

Ripe fruits are often attacked by ants, probably on account of the sugar they contain; and, for the same reason, the buds of trees are infested with these insects, and often injured by their depredations. There is no evidence that they at any time feed upon corn or other vegetable seed. This point has been well established by Mr Gould; and Bonnet, who kept a colony of ants prisoners in his study, observed, that, however long they had been kept without food, still they never touched the corn that he put before them. Honey and sweetmeats have strong attractions for ants, who, if they once discover their way to a magazine of these dainties, will immediately communicate the tidings to the rest of the society, and, leading them to the spot, a regular path will soon be established, which will continue to be crowded with a train of depredators so long as any thing remains to be pilfered. It is, however, certain, notwithstanding the assertion of Bomare, who compares them to the miser, whose chief pleasure consists in contemplating the riches he has amassed in his coffers, that ants are not in the habit of hoarding provisions for future consumption. They grow torpid when the cold exceeds 27° of Fahrenheit, and in that state require no food; and the aphis affords them sufficient nourishment at other periods of the winter.

Their nests

In building their nests, each species of ant follows its own peculiar mode of construction, and employs different materials for this purpose. Many form them of clay, and particularly the smaller species; one set building up a regular series of apartments in successive stories, often forty in number, with materials which are furnished to them by another set of workers, who are excavating the ground below. The cielings are supported throughout by small pillars in some parts, and by vertical walls in others; while broad arches are in other places raised, in order to protect larger spaces, and to admit of lengthened passages of communication throughout a long extent of apartments. These ants can proceed in the building only at such times as the earth has been softened by rain or dew, and the atmosphere is at the same time sufficiently moist to allow of the materials cohering firmly before they dry. Such are probably the ants which Pliny mentions as working by moonlight. On one occasion, when the ants, under the inspection of Mr Huber, had discontinued their labours on account of too great dryness in the atmosphere, he succeeded in getting them to renew their operations by sprinkling water upon them with a wet brush, in imitation of a natural shower. They carefully close the doors of their habitations every night, in order to prevent the intrusion of other insects; and a few remain on the outside during the night as sentinels, to give alarm in case of danger. Some species of ants collect fragments of leaves, of bark, or of straw, with which they construct more permanent and artificially constructed nests than the former. Others employ nothing but the fine powder which they collect from decayed wood. Some, for greater security, establish themselves under a large stone, or in the crevices of decayed buildings. Several tribes, on the other hand, penetrate into the solid substance of wood, which they scoop out into numerous cells, leaving only intermediate partitions of extreme tenuity, just of the strength sufficient to enable the whole fabric to support itself; while it crumbles into powder when pressed between the fingers.

Fecundation, and growth of their young.

We shall now take a brief review of the principal circumstances relating to the fecundation of the ant, and the evolution and growth of the young. The former is effected very generally during the flight of the females, in which they are accompanied by the males; both appearing to be provided with wings chiefly for this object. A certain number of the females that are impregnated, are also, by the assistance of their wings, enabled to reach distant situations, where they become respectively the founders of new colonies. The males, on the other hand, having fulfilled the office for which nature had destined them, are left to perish on the spot where they descend, being removed from those who formerly administered to them food, and being destitute of the means of procuring subsistence for themselves. Immense swarms of ants are occasionally met with; and some have been recorded of such prodigious density and magnitude as to darken the

[1] *Biblioteca Italiana*, tomo xv. p. 217.

Ant.

air like a thick cloud, and to cover the ground to a considerable extent where they settled. Mr Gleditsch describes, in the *History of the Berlin Academy* for 1749, shoals of a small black ant which appeared in Germany, and formed high columns in the air, rising to a vast height, and agitated with a curious intestine motion, somewhat resembling the aurora borealis. A similar flight of ants is spoken of by Mr Acolutte, a clergyman of Breslaw, which resembled columns of smoke, and which fell on the churches and the tops of the houses, where the ants could be gathered by handfuls. In the German *Ephemerides*, Dr Charles Rayger gives an account of a large swarm, which passed over the town of Posen, and was directing its course towards the Danube. The whole town was strewed with ants, so that it was impossible to walk without trampling on thirty or forty at every step. And more recently, Mr Dorthes, in the *Journal de Physique* for 1790, relates the appearance of a similar phenomenon at Montpellier. The shoals moved about in different directions, having a singular intestine motion in each column, and also a general motion of rotation. About sunset they all fell to the ground; and, on examining the ants, they were found tc belong to the *Formica nigra* of Linnæus.

The swarming of ants does not appear to be at all analogous to that of bees: its object seems to be confined to the propagation of the species, and is not the result of any co-operation of numbers, who associate together in search of a new habitation, in which an already populous assemblage may establish themselves. It would appear that the infant colonies consist of very small numbers, and are perhaps wholly the offspring of a common parent, who has migrated alone, or with but a few companions. The greater number of impregnated females alighting in the neighbourhood of the nest, are laid hold of by the labouring ants, who drag them to the nest, where they keep them prisoners till they are ready to deposit their eggs. It is very generally asserted that they also deprive them of their wings; but the later observations of M. Huber disprove that opinion. The impregnated females cast their wings of their own accord. They twist and contort these organs in various directions, till they finally drop off. Such as are unimpregnated have not been observed to perform this singular action. Each female is at this period attended by a numerous retinue of labourers, who treat her with the greatest deference, and are solicitous to anticipate all her wants. Contrary to what happens among bees, many females inhabit the same nest, and live together in the utmost harmony. The eggs, when first deposited, are very small, but become considerably larger before the larva is excluded, being apparently nourished by absorption; for the ants to whose care they are confided are perpetually licking them with their tongues,—a fact which, however curious, is by no means a solitary one in the history of insects. The larva comes forth at the end of a fortnight, and appears in the form of a transparent maggot, with a head and wings, but without any external organs of motion. They are in this state fed by their nurses with a fluid disgorged from their stomachs; and, in the course of their transformation to the state of nympha, and of perfect insect, are still dependent upon their assistance. These affectionate guardians help them to extricate themselves from the web of the cocoon, to unfold the duplicatures of their wings, and supply them with food, till they are capable of procuring it for themselves. The young ant is an exceedingly tender and delicate animal, easily destroyed by any considerable variation of temperature, or by excessive humidity; and great care and attention appear to be required to bring it to maturity: it appears to be the constant business of the ants which remain at home to convey them to different parts of the nest, where the temperature is suited to them; and whenever danger threatens they show the utmost solicitude to remove them to situations of security.

Their sagacity

Very different degrees of sagacity belong to different tribes of ants. Many traits in the history of the larger kinds, as related by Huber, are of so singular a character as to be scarcely credible if we had received them from a less reputable authority, and if we were not already prepared to admit them, from our knowledge of many equally curious circumstances in the economy of bees, which have been established by the concurrent testimony of the most scrupulous observers. Some tribes of ants, according to this naturalist, who are peculiarly fond of the honey which exudes from the aphis, convey many of these insects into their own nests, lodging them near the vegetables on which they feed, but keeping them prisoners within their habitations, and assigning to them distinct apartments in the subterranean recesses of their dwellings. As if conscious of the future advantages they may derive from these insects, they collect their eggs, and superintend their hatching with the same care which they bestow on the eggs of their own species. The aphis lives in perfect harmony with its keepers, who, so far from molesting it, defend it with courage against ants belonging to other nests, who frequently attempt to get possession of them. Occasionally they are lodged by the ants in fortified buildings, which they construct at a distance from the nest, in situations where they are most secure from invasion. The aphis is not the only genus of insect which furnishes this kind of provision to the ant; the kermes and gall-insect are employed occasionally for the same purpose, and are found domesticated in the nests of ants, at the same time that they contain several species of aphis, and from all of which they collect nutriment.

Their wars.

This picture of domestic harmony is strongly contrasted with the scenes of ferocious contention which are occasionally exhibited between the inhabitants of neighbouring nests; nature appearing to have instilled, together with the love of social order, the same passions of rivalry, of ambition, and of revenge, of which we deplore the operation among beings of a higher order. War, the scourge of the human species, exerts its desolating power among the tribes of gregarious insects, and tends to check their otherwise excessive increase of number. The battles which take place between rival colonies of ants are often on a scale of prodigious magnitude: millions of combatants engage on either side with a fury and pertinacity that is truly astonishing. Their weapons of offence are the jaws, which are capable of inflicting a deep bite, and of instilling into the wound a highly acrid liquor; and also, in many species, a sting resembling in situation and structure that of the bee, and likewise containing a venomous juice. The liquor is well known to possess acid properties, and is now found to consist of two acids, and a volatile one, the *formic*, of which the constitution is $C_2 H_2 O_4$. It has been ascertained by the German chemist Döbereiner, that an acid analogous to this animal secretion may be artificially obtained by chemical means. See CHEMISTRY. It is extremely volatile and pungent, and is capable of being thrown out by the ant, when irritated, in considerable quantities. Roux, in the *Journal de Médicine* for 1762, reports a number of experiments which were made by exposing animals to its influence. Frogs were killed by the vapour from an ant's nest in less than five minutes; and persons breathing it, when of a certain intensity, were nearly suffocated, or were seized with fever, followed by an extensive cutaneous eruption, which terminated in desquamation of the cuticle.

Some of the most daring and courageous species, such as that which M. Huber calls the *Amazon-ant*, make it the business of their lives to attack the nests of the weaker species, and succeed, after a desperate conflict, in plundering them of their eggs and larvæ, which they convey to their own nests. These are hatched and reared by ants of the same species as themselves, who may be considered as auxiliaries to the amazons, and who had themselves, at some former period, been kidnapped from their parent nest by the amazons. Thus, a society is formed among different species of insects, to which no parallel exists but in the human race. The amazons live without labour; they are attended, fed, and cherished by the ants which they have procured by this kind of slave-trade, and who take as much care of their offspring as they do of those of their own species. Perfect order is preserved, and the natural instinct of hostility, which in another condition of the society exists between the two tribes, seems in the auxiliaries completely extinguished, by their being educated with the race of their original oppressors.

Ants have numerous enemies among quadrupeds and birds; and some, as the ant-eater, dasypus, and manis or pangolin, together with the tribe of woodpeckers, devour a very large proportion. The *Formica leonis*, or myrmelion, feeds almost wholly on these insects. The bees at the Cape, according to Mr Campbell, frequently drive out the ants from their nests, of which they take possession themselves. Ants are also infested by lice, which, as may well be imagined, are so minute as to be invisible without the assistance of a very high magnifying power. They are stated by Redi, who discovered them, to resemble in shape those of the fowl and the dove.

Mode of destroying ants.

The most effectual mode of destroying ants is to pour boiling water into their nests, which destroys at once both the perfect insects and their eggs and larvæ; so that those who, being from home, had escaped the general catastrophe, finding it impossible to repair the loss, abandon the spot, and disperse. The addition of urine, or of soot, or still better of tobacco, which may be infused in the water, will render it much more efficacious. A decoction of walnut-leaves or lime-water will also generally answer. The night is the best time for applying these remedies, as the ants are then all collected in the nest. Arsenic is exceedingly destructive to ants, and affords another ready mode of getting rid of those that intrude into cupboards or pantries: it may, for this purpose, be mixed with sugar, or kneaded with any kind of provision, and placed in the paths they are observed to frequent. Corrosive sublimate is also highly poisonous to them, and myriads of the sugar-ants at Grenada were destroyed by means of it; and it is stated to have had the effect of rendering the ants so outrageous that they destroyed each other, as could be seen by a magnifying glass, and even, though less distinctly, by the naked eye. It appears also that this effect was produced even when they only came in contact with the poison. The whole island, however, was so overrun with these ants, that the numbers that could be destroyed by these means bore no sensible proportion to the whole; and recourse was had to fire as more applicable to destruction on a larger scale. It was observed that when wood, burnt to the state of charcoal, without flame, and immediately taken from the fire, was laid in their way, they crowded to it in such amazing numbers as soon to extinguish it, though thousands perished by so doing. Holes were therefore dug at proper distances in a cane-piece, and fire made in each of them. Prodigious quantities perished in this way; for those fires, when extinguished, appeared in the shape of mole-hills, from the numbers of dead that were heaped upon them. But as none of the females or young brood were destroyed by this expedient, the ants soon re-appeared in as great numbers as before; and the island would probably have continued subject to this scourge, had it not been for the occurrence of the great hurricane of 1780, which at once cleared all the islands of this dreadful pest, by which the sugar-cane plantations had been threatened with total ruin. (P. M. R.)

For the specific descriptions and systematic arrangement of the different kinds of ants, see ENTOMOLOGY.

Ant-Eater. See MAMMALIA, *Index*.

Ant-Hills are little hillocks of earth which the ants throw up for their habitation and the breeding of their young. They are a very great mischief to dry pastures, not only by wasting so much land as they cover, but by hindering the scythe in mowing the grass, and yielding a poor hungry food, pernicious to cattle. The manner of destroying them is to cut them into four parts from the top, and then dig into them so deep as to take out the core below, so that when the turf is laid down again it may lie somewhat lower than the level of the rest of the land. By this means it will be wetter than the rest of the land, and this will prevent the ants from returning to the same place, which otherwise they would certainly do. The earth that is taken out must be scattered to as great a distance every way as may be, otherwise they will collect it together, and make another hill just by. The proper time for doing this is winter; and if the places be left open, the frost and rains of that time of the year will destroy the rest; but in this case care must be taken that they are covered up early enough in the spring, otherwise they will be less fertile in grass than the other places. In Hertfordshire they use a particular kind of spade for this purpose. It is very sharp, and formed at the top into the shape of a crescent, so that the whole edge makes up more than three fourths of a circle; this cuts in every part, and does the business very quickly and effectually. Others use the same instruments that they do for mole-hills. Human dung is a better remedy than all these, as is proved by experiment; for it will kill great numbers of them, and drive all the rest away, if only a small quantity of it be put into their hills.

ANTACIDS, an appellation given to all medicines proper to correct acid in the stomach. Under the class of antacids come, 1. Absorbents, as chalk, magnesia, carbonates of the alkalies, and pure alkalies; 2. Obtundents, as oils and fats.

ANTÆ. See ARCHITECTURE.

ANTÆOPOLIS, in *Ancient Geography*, the capital of the Nomos Antæopolites, was situated on the right bank of the Nile, in Lat. 27. 11. N. Its site is now occupied by the village of Gau-el-Kebir.

ANTÆUS, in *Fabulous History*, a giant of Libya, son of Neptune and Terra. Designing to build a temple to his father of men's skulls, he slew all he met. In his combat with Hercules he is said to have received strength from the earth every time he was thrown upon it, which Hercules perceiving, lifted him up from the ground and squeezed him to death.

ANTALO, a considerable town of Abyssinia, capital of the flat and fertile district of Enderta, which is dependent on Tigré. It contains not more than 1000 houses, which, with the exception of that destined for the residence of the Ras or sovereign of Tigré, are no better than clusters of huts, with conical thatched roofs.

ANTANACLASIS (ἀντί and ἀνακλάω), literally a reflexion or echo, in *Rhetoric*, a figure which repeats the same word, but in a different sense; as, *dum vivimus, vivamus*.

ANTANAGOGE (ἀντί and ἀναγωγή), in *Rhetoric*, a figure by which, when the accusation of the adversary is unanswerable, we charge him with the same or other crimes.

ANTAR, the hero of an Arabian romance, translated, in

1819, by Hamilton, who was long secretary to the British embassy at Constantinople. Antar was a real personage, a Bedouin Arab, who by his valour and enterprise raised himself to distinction about the close of the fifth century.

ANTARCTIC, in a general sense, denotes something opposite to the northern or arctic pole. Hence antarctic circle is one of the lesser circles of the sphere, and distant only 23° 30′ from the south pole, which is likewise called antarctic for the same reason. See Polar Regions.

ANTARES, or the Scorpion's Heart, in *Astronomy*, the name of a double star, having a small and very close companion. Its R.A. on 1st January 1853, was 16 h. 20 m. 24·020 s.; D. 26° 6′ 3·99″.

ANTEAMBULONES, in *Roman Antiquity*, servants who went before persons of distinction to clear the way before them. They used this formula, *Date locum domino meo*, i. e., Make room, or way, for my master; and whenever this exclamation did not suffice, they made free use of their hands and elbows.

ANTECESSOR, one that goes before. It was an appellation given to those who excelled in any science. Justinian applied it particularly to professors of the civil law; and, in the universities of France, the teachers of law used to take the title of *antecessors* in all their theses.

ANTECURSORES, in the *Roman Armies*, a party of horse detached before, partly to get intelligence, provisions, &c., and partly to choose a proper place to encamp in. These were otherwise called *antecessores*, and by the Greeks πρόδρομοι.

ANTEDILUVIANS, a general name for all mankind who lived before the flood, thus including the whole of the human race from Adam to Noah and his family.

As Moses has not set down the particular time of any transaction before the flood, except only the years of the fathers' ages in which the several descendants of Adam in the line of Seth were begotten, and the length of their several lives, it has been the business of chronologers to endeavour to fix the years of the lives and deaths of those patriarchs, and the distance of time from the Creation to the Deluge. In this there could be little difficulty were there no varieties in the several copies we now have of Moses's writings; which are, the Hebrew, the Samaritan, and the Greek version of the Septuagint; but as these differ very considerably from one another, learned men have been much divided in opinion concerning the chronology of the first ages of the world.

That the reader may the better judge of the variations in the three copies in this period, they are exhibited in the following table, with the addition of those of Josephus as corrected by Dr Wells and Mr Whiston.

A Table of the Years of the Antediluvian Patriarchs.

	Their Ages at their Sons' Birth.				Years they lived after their Sons' Birth.			Length of their Lives.		
	Heb.	Sam.	Sept.	Jos.	Heb.	Sam.	Sept.	Heb.	Sam.	Sept.
Adam	130	130	230	130	800	800	700	930	930	930
Seth	105	105	205	105	807	807	707	912	912	912
Enos	90	90	190	90	815	815	715	905	905	905
Cainan	70	70	170	70	840	840	740	910	910	910
Mahalaleel	65	65	165	65	830	830	730	895	895	895
Jared	162	62	162	62	800	785	800	962	847	962
Enoch	65	65	165	65	300	300	200	365	365	365
Methuselah	187	67	167	187	782	653	802	969	720	969
Lamech	182	53	188	182	595	600	565	777	653	753
Noah was aged at the Flood	600	600	600	600						
To the Flood	1656	1307	2242	1556						

All our authentic information respecting this long and interesting period is contained in 49 verses of Genesis (iv. 16, to vi. 8), more than half of which are occupied with a list of names and ages, invaluable for chronology, but conveying no particulars regarding the primeval state of man. Some additional information, though less direct, may be safely deduced from the history of Noah and the first men *after* the Deluge; for it is very evident that society did not begin afresh after that event; but that, through Noah and his sons, the new families of men were in a condition to inherit, and did inherit, such sciences and arts as existed before the Flood. This enables us to understand how settled and civilised communities were established, and large and magnificent works undertaken, within a few centuries of the Deluge.

The human race probably had before the Deluge whatever knowledge or civilisation their agricultural and pastoral pursuits required. It is remarkable that of the strictly savage or hunting condition of life there is not the slightest trace before the Deluge. After that event, Nimrod, although a hunter (Gen. x. 9), was not a savage, and did not belong to hunting tribes of men. In fact, savagism is not discoverable before the confusion of tongues, and was in all likelihood a degeneracy from a state of cultivation, eventually produced in particular communities by that great social convulsion. That a degree of cultivation was the primitive condition of man, from which savagism in particular quarters was a degeneracy, and that he has not, as too generally has been supposed, worked himself up from an original savage state to his present position, has at least been powerfully argued by Dr Philip Lindsley, and is strongly corroborated by the conclusions of modern ethnographical research; from which we learn that, while it is easy for men to degenerate into savages, no example has been found of savages rising into civilisation but by an impulse from without, administered by a more civilised people; and that, even with such impulse, the *vis inertiæ* of established habits is with difficulty overcome.

All that was peculiar in the circumstances of the antediluvian period was eminently favourable to civilisation. "The *longevity* of the earlier seventeen or twenty centuries of human existence is a theme containing many problems. It may be here referred to for the purpose of indicating the advantages which must necessarily have therefrom accrued to the mechanical arts."

By reason of their length of life, the antediluvians had also more encouragement in protracted undertakings, and stronger inducements to the erection of superior, more costly, more durable, and more capacious edifices and monuments, public and private, than exist at present.

But probably the greatest advantage enjoyed by the antediluvians, and which must have been in the highest degree favourable to their advancement in the arts of life, was the uniformity of language. Nothing could have tended more powerfully to maintain, equalise, and promote whatever advantages were enjoyed, and to prevent any portion of the human race from degenerating into savage life.

The opinion that the old world was acquainted with *astronomy*, is chiefly founded on the ages of Seth and his descendants being particularly set down (Gen. v. 6, *sqq.*), and the precise year, month, and day being stated in which Noah and his family, &c., entered the ark, and made their egress from it (Gen. vii. 11; viii. 13).

That the antediluvians were acquainted with *music* is certain; for it is expressly said that Jubal (while Adam was still alive) became 'the father of those who handle the כִּנּוֹר *kinnur* and the עוּגָב *hugab*.' The *kinnur*, was evidently a stringed instrument resembling a lyre; and the *hugab* was without doubt the pandæan pipe, composed of reeds of different lengths joined together.

With regard to *architecture*, it is a singular and important fact that Cain, when he was driven from his first abode, built a city in the land to which he went, and called it Enoch, after his son. This shows that the descendants of Adam lived in houses and towns from the first, and consequently affords another confirmation of the argument for the original cultivation of the human family.

That they were acquainted with *agriculture*, is obvious from a reference to the case of Noah, who, immediately after the Flood, became a husbandman, and planted a vineyard. He also knew the method of fermenting the juice of the grape; for

it is said that he drank of the wine, which produced inebriation (Gen. ix. 20, 21). This knowledge he doubtless obtained from his progenitors anterior to the destruction of the old world.

It is impossible to speak with any decision respecting the form or forms of government which prevailed before the Deluge. The slight intimations to be found on the subject seem to favour the notion that the particular governments were patriarchal, subject to a general theocratical control—God himself *manifestly* interfering to uphold the good and check the wicked. The right of property was recognised, for Abel and Jabal possessed flocks, and Cain built a city. As ordinances of religion sacrifices certainly existed (Gen. iv. 4), and some think that the sabbath was observed; while some interpret the words, "Then men began to call upon the name of the Lord" (Gen. iv. 26), to signify that public worship then began to be practised.

Marriage, and all the relations springing from it, existed from the beginning (Gen. ii. 23–25); and although polygamy was known among the antediluvians (Gen. iv. 19), it was most probably unlawful; for it must have been obvious that, if more than one wife had been necessary for a man, the Lord would not have confined the first man to one woman. The marriage of the sons of Seth with the daughters of Cain appears to have been prohibited, since the consequence of it was that universal depravity in the family of Seth so forcibly expressed in this short passage, "*All* flesh had corrupted its way upon the earth" (Gen. vii. 11).—*Critica Biblica*, iv. 14–20; Faber's *Horæ Mosaicæ;* P. Lindsley, D.D., *On the Primitive State of Mankind*, in *Am. Bib. Repos.* iv. 277–298; vi. 1–27. See also *Anc. Univ. Hist.* i. 142–201.—*Cyclopædia of Biblical Literature*, by Kitto.

ANTEGO. See Antigua.

ANTEJURAMENTUM, by our ancestors called *juramentum calumniæ*, an oath which anciently both accuser and accused were to take before any trial or purgation. The accuser was to swear that he would prosecute the criminal; and the accused to make oath, on the day he was to undergo the ordeal, that he was innocent of the crime charged against him.

ANTELOPE. See Mammalia, *Index*.

ANTELUCAN, (*ante* and *lux*) denotes what occurs during the night, or before day. We find frequent mention of the antelucan assemblies (*Cœtus antelucani*) of the ancient Christians in times of persecution for religious worship.

ANTEMNAE, a very ancient city of Latium, situated immediately below the confluence of the Anio with the Tiber. Being only three miles from Rome, the inhabitants were soon engaged in war with that rising city, but were vanquished by Romulus, and became a dependency of Rome. No traces of this city remain.

ANTEMURALE, in the *Ancient Military Art*, denotes much the same with what the moderns call an *outwork*.

ANTENATI, in *Modern English History*, is chiefly understood of the subjects of Scotland born before King James the First's accession to the English crown, and alive after it. In relation to these, those who were born after the accession were denominated *Postnati*. The antenati were considered as aliens in England, whereas the postnati claimed the privilege of natural subjects.

ANTENCLEMA, (ἀντὶ and ἔγκλημα) in *Oratory*, is where the whole defence of the accused turns on criminating the accuser. Such is the defence of Orestes, or the oration for Milo: *Occisus est, sed latro: Exsectus, sed raptor.*

ANTENOR, an Athenian sculptor, B.C. 509, celebrated for his bronze statues of Harmodius and Aristogiton. Winkelmann calls him Agenor.

Antenor, a Trojan prince, said to have come into Italy: he expelled the Euganians on the river Po, and built the city of Padua, where his tomb is said to be still extant.

ANTEPILANI, in the *Roman Armies*, the first two lines of troops, consisting of the *Hastati* and *Principes*, in contradistinction to the third line, the *Triarii*, who were called *Pilani*.

ANTEQUERA, a city of Spain, in the province of Malaga. It is situate in a beautiful and fertile valley, covered with olive-trees, around which, in all directions, lofty mountains rise to a great height, which contain valuable quarries of marble of every description. Near it is a saline lake, which supplies the inhabitants of the district with salt for all their culinary purposes. As long as the Moors possessed the kingdom of Granada, this city, from being the point which commands the southern entrance to the plain, was a military post of vast importance, and its possession was perpetually contested by the rival monarchs on both sides of it. An ancient castle still remains, in which are preserved specimens of the various military weapons and accoutrements both of the Moors and the Christians of the fourteenth century. It contains about 17,000 inhabitants, employed in agriculture and in the manufacture of cloth and leather.

ANTEROS, in *Mythology*, one of the two Cupids. They are placed at the foot of the Venus de Medici. Anteros is represented with a heavy and sullen look, agreeably to the poetical description of him, as the cause of love's ceasing. The other was called Eros.

ANTESIGNANI, in the *Roman Armies*, the first line or first body of troops, so called from their being placed before the standards.

ANTESTARI, in *Roman Antiquity*, signifies to bear witness against any one who refused to make his appearance in the Roman courts of judicature on the day appointed, and according to the tenor of his bail. The plaintiff finding the defendant after such a breach of his engagement, was allowed to carry him into court by force, having first asked any of the persons present to bear witness. The person asked to bear witness in this case expressed his consent by turning his right ear, which was instantly taken hold of by the plaintiff; and this was to answer the end of a subpœna. The ear was touched upon this occasion, says Pliny, as being the seat of memory, and therefore the ceremony was a sort of caution to the party to remember his engagement.

ANTHELMINTICS, remedies against intestinal worms.

ANTHEM, a church song performed in cathedral service by choristers, who sung alternately. It was used to denote both psalms and hymns when performed in this manner; but at present, anthem is used in a more confined sense, being applied to certain passages of the Scriptures adapted to a particular solemnity. Anthems were first introduced, in the reformed service of the English church, in the beginning of the reign of Queen Elizabeth.

ANTHEMIS, a genus of plants of the natural order of the Compositæ, to which belong *A. nobilis* or chamomile, *A. tinctoria*, *A. Pyrethrum*.

ANTHEMIUS, a celebrated architect of the time of Justinian, to whom we are indebted for the church of Sta Sophia at Constantinople. He was the first architect who ventured "to suspend a cupola in air." Its diameter of 115 feet, and its perfect preservation, after the lapse of more than thirteen centuries, shows the boldness of the architect's conception, and the scientific skill of its execution. He did not live to see the temple completed, having died in 554: Sta Sophia was not finished until three years thereafter.

ANTHESPHORIA, in *Antiquity*, a Sicilian festival in honour of Persephone. The word is derived from ἄνθος, *flower, and* φέρω, *I carry;* because that goddess was forced away by Pluto when she was gathering flowers in the fields. Yet Festus does not ascribe the feast to Persephone, but says it was thus called because ears of corn were carried on this day to the temples. Anthesphoria seems to be the same thing with the *florifertum* of the Latins, and answers to the harvest-home among us.

ANTHESTERIA, in *Antiquity*, was a feast celebrated by the Athenians in honour of Bacchus. The most natural derivation of the word is from the Greek ἄνθος (*flos*), a

flower, it being the custom at this feast to offer garlands of flowers to Bacchus.

The anthesteria lasted three days, the 11th, 12th, and 13th of the month, each of which had a name suited to the proper office of the day. The first day of the feast was called πιθοιγία, because on this day they tapped the vessels and tasted the wine of the preceding year. The second day they called χόες, from χοῦς, the cup, and seem to have devoted it to drinking; on this they practised the *Ascolia*, with other merriments. The third day they called χύτροι, *kettles:* on this day they boiled all sorts of pulse in kettles; which, however, they were not allowed to taste, as being offered to Hermes.

ANTHESTERION, in *Ancient Chronology*, the eighth month of the Athenian year. It contained 29 days, and answered nearly to our February. It received its name from the festival anthesteria kept in it.

ANTHOLOGION, the title of the service-book used in the Greek church. It is divided into 12 months, containing the offices sung throughout the year, on the festivals of our Saviour, the Virgin, and other remarkable saints.

ANTHOLOGY, a discourse of flowers, or a selection of beautiful passages from various authors. It is also the name given to a collection of epigrams from Greek poets.

ANTHONY, Saint, was born in Egypt in 251, and inherited a large fortune, which he distributed among his neighbours and the poor, retired into solitude, founded a religious order, built many monasteries, and died A.D. 356. Many ridiculous stories are told of his conflicts with the devil, and of his miracles. There are seven epistles extant attributed to him.

St Anthony is sometimes represented with a fire by his side, signifying that he relieves persons from the inflammation called after his name; but always accompanied by a hog, on account of his having been a swine-herd, and curing all disorders in that animal. To do him the greater honour, the Romanists in several places keep at common charges a hog denominated *St Anthony's hog*, for which they have great veneration. Some have St Anthony's picture on the walls of their houses, hoping thereby to be preserved from the plague; and the Italians who do not know the true signification of the fire painted at the side of their saint, concluding that he preserves houses from being burnt, invoke him on such occasions. Painters and poets have made very free with this saint and his followers; the former by the many ludicrous pictures of his temptation, and the latter by various epigrams on his disciples.

Anthony, or *Knights of St Anthony*, a military order instituted by Albert duke of Bavaria, when he designed to make war against the Turks in 1382. The knights wore a collar of gold made in form of a hermit's girdle, from which hung a stick cut like a crutch, with a little bell, as they are represented in St Anthony's pictures.

St Anthony's Fire, a name given to the erysipelas. It was so named from the saint above mentioned, who was especially invoked for its cure.

ANTHOPHORUM, in *Botany*, the columnar process within the calyx, upon which the petals, stamens, and pistil are placed.

ANTHORISMUS (from ἀντί and ὅρος), in *Rhetoric*, a definition of a thing contrary to that given by the adverse party. Thus, if the plaintiff urge, that to take any thing away from another without his knowledge or consent, is a theft; this is called ὅρος, or definition. If the defendant reply, that to take a thing away from another without his knowledge or consent, but with the design to return it to him again, is not theft; this is an ανθορισμος.

ANTHRACITE, or *blind coal*, which burns without flame. Kilkenny coal is of this kind. See Coal.

ANTHRAX, a Greek term, literally signifying a burning coal, used by the ancients to denote a gem, as well as a disease more generally known by the name of *carbuncle*.

ANTHROPOGLOTTUS, among *Zoologists*, an appellation given to such animals as have tongues resembling that of mankind, particularly to the parrot kind.

ANTHROPOLOGY, a discourse upon human nature. It is sometimes applied to designate the speculations and inquiries that have obtained concerning the varieties of the human race. See Man.

ANTHROPOMORPHISM, a term in theology used to denote that figure whereby words derived from *human* objects are employed to express something which relates to the Deity. As a finite being can have no intuitive knowledge of an infinite, so no language of rational creatures can fully express the nature of God and render it comprehensible. All further knowledge of God must be communicated by words used to express ourselves intelligibly concerning human and other terrestrial objects. Such words and phrases have their foundation in a resemblance, which, according to our conceptions, exists between the Deity and mankind.

Anthropomorphitic phrases, generally considered, are such as ascribe to the Deity mixed perfections and human imperfections. These phrases may be divided into three classes, according to which we ascribe to God:—1. Human actions (ἀνθρωποποίησις). 2. Human affections, passions, and sufferings (ἀνθρωποπαθεία). 3. Human form, human organs, human members (ἀνθρωπομόρφισμος).

A rational being, who receives impressions through the senses, can form conceptions of the Deity only by a consideration of his own powers and properties. Anthropomorphitic modes of thought are therefore unavoidable in the religion of mankind; and although they can furnish no other than corporeal or sensible representations of the Deity, they are nevertheless true and just when we guard against transferring to God qualities pertaining to the human senses. It is, for instance, a *proper* expression to assert that God *knows* all things; it is improper, that is, tropical or anthropomorphitic, to say that He *sees* all things. Anthropomorphism is thus a species of *accommodation*, inasmuch as by these representations the Deity, as it were, lowers himself to the comprehension of men. And it is altogether consonant to his wisdom and benevolence in communicating divine revelations to address mankind in language adapted to their inferior capacities. Therefore it is that this figure is called by the Fathers *Divine Economy* (Theodoret, *Dialog.* 2.) and *Condescension* (Gregory of Nazianzus, *Orat.* 1).

ANTHROPOMORPHITES, in *Ecclesiastical History*, a sect of ancient heretics, who, taking every thing spoken of God in Scripture in a literal sense, particularly that passage of Genesis in which it is said *God made man after his own image*, maintained that God had a human shape. They are likewise called *Audeans*. See Audeus. The modern doctrine of the Mormonites is of the same tenor with this.

ANTHROPOMORPHOUS, something that bears the figure or resemblance of a man. Naturalists give instances of anthropomorphous plants, anthropomorphous minerals, &c. These generally come under the class of what are called *lusus naturæ*, or monsters.

ANTHROPOPHAGI (of ἄνθρωπος, *a man*, and φάγειν, *to eat*, Men-Eaters). That there have been, in almost all ages of the world, nations who have followed this barbarous practice, we have abundant testimony.

The Cyclopes, the Læstrygons, and Scylla, are all represented in Homer as *Anthropophagi*, or man-eaters; and the female phantoms, Circe and the Sirens, first bewitched with a show of pleasure, and then destroyed. This, like the other

parts of Homer's poetry, had a foundation in the manners of the times preceding his own. According to Herodotus, among the Essedonian Scythians, when a man's father died, the neighbours brought several beasts, which they killed, mixed up their flesh with that of the deceased, and made a feast. Among the Massagetæ, when any person grew old, they killed him and ate his flesh; but if he died of sickness they buried him, esteeming him unhappy. The same author also assures us that several nations in the Indies killed all their old people and the sick, to feed on their flesh. He adds, that persons in health were sometimes accused of being sick, to afford a pretence for devouring them. According to Sextus Empiricus, the first laws that were made were for the preventing of this barbarous practice, which the Greek writers represent as universal before the time of Orpheus.

Of the practice of anthropophagy in later times, we have the testimonies of all the Romish missionaries who have visited the interior parts of Africa, and even some parts of Asia. When America was discovered, this practice was found to be almost universal, so that several authors have attributed it to a want of other food, or the indolence of the people to seek for it; though others ascribe its origin to a spirit of revenge. It prevailed to an almost incredible extent among the ancient Mexicans, by whom it was associated with their religious ceremonies, and that at a time when they had attained to a comparatively high civilisation and refinement. (See Prescott's *History of the Conquest of Mexico*. Lond. 1843. Vol. i. p. 71–76, &c.)

It appears pretty certain, from recent investigations, that the New Zealanders, inhabiting a country where the larger animals were unknown, were accustomed to devour the bodies of their enemies, and were even epicures in the choice of human flesh. This may have arisen originally from a deficiency of animal food, but cannot be ascribed, as a systematic practice, to the cravings of starvation; for deficiency of all food must have limited population; and that sustenance which fed the victims must have supplied the necessities of their immolators. There can be no doubt that cannibalism has prevailed in some ages and rude societies; but when we reflect how often national hatred has brought this same charge against a detested people, as in the mutual recriminations of the Saracens and Christians of the west, we must receive the accounts of the systematic anthropophagy of various nations, by our early voyagers and travellers, as either gross exaggerations or fictions. (See *Cruise's Voyage; New Zealanders—Lib. Ent. Knowl.*)

Mr Marsden informs us that this horrible custom is practised by the Battas, a people in the island of Sumatra. "They do not eat human flesh," says he, "as a means of satisfying the cravings of nature, owing to a deficiency of other food; nor is it sought after as a gluttonous delicacy, as it would seem among the New Zealanders. The Battas eat it as a species of ceremony; as a mode of showing their detestation of crimes, by an ignominious punishment; and as a horrid indication of revenge and insult to their unfortunate enemies. The objects of this barbarous repast are the prisoners taken in war, and offenders convicted and condemned for capital crimes." This has been confirmed by Raffles.

It may be said, that whether the dead body of an enemy be eaten or buried is a matter perfectly indifferent. But whatever the practice of eating human flesh may be in itself, it certainly is relatively, and in its consequences, most pernicious. It manifestly tends to eradicate a principle which is the chief security of human life, and more frequently restrains the hand of the murderer than the sense of duty r the dread of punishment. Even if this horrid practice originates from hunger, still it must be perpetuated from revenge. Death must lose much of its horror among those who are accustomed to eat the dead; and where there is little horror at the sight of death, there must be less repugnance to murder.

ANTHYPOPHORA, in *Rhetoric*, a figure of speech, being the counterpart of an hypophora. See HYPOPHORA.

ANTI (ἀντί), a Greek preposition, which forms part of many compounded words, meaning against or opposite; sometimes it refers to place, as Antiparos, sometimes to character, as Antichrist.

ANTIARINE, and ANTIARIS. The last is the name of a genus of poisonous plants, to which the noted upas tree of Java belongs. Antiarine is the chemical constituent of this poison, which is obtained from the inspissated juice of the plant in shining whitish crystals, soluble in water. The fables relating to the upas tree may be seen in the notes to *The Botanic Garden*, of Darwin; the real history of the plant in Dr Horsfield's paper in vol. 7, *Batavian Transactions*, and Raffle's *Java*, vol. i. 44. The native name of this tree is *anchar*. It is a *monœcious* plant, growing with a stem to the height of 70 or 80 feet. The bark is whitish, and on being wounded, yields the yellowish-white poisonous juice in large quantity. The stem sends off a few stout branches nearly horizontal, which subdivide into an irregular hemispheric crown. It is only found in deep forests, in fertile soils. The inner bark is fibrous; and when long steeped in water is formed into coarse cloth, like the finer bark of the *Morus papyrifera*, but it is apt to inflame the skin when worn, unless thoroughly beaten and long soaked in water.

ANTIBACCHIUS, in *Ancient Poetry*, a foot consisting of three syllables, the first two long, and the last one short: such is the word āmbīrĕ.

ANTIBES, anciently *Antipolis*, a strongly fortified seaport town of France, in the department of Var, situated on the Mediterranean, 10 miles south-east of Grasse. Its port is good and easy of access, with a lighthouse on a rock at the entrance. Population in 1846, 4515, chiefly engaged in the fishing and curing of sardines and anchovies, and in trading in dried fruits and oil. Lat. 43. 34. 40. N. Long. 7. 7. 50. E.

ANTICHRIST. The meaning attached to this word has been greatly modified by the controversies of various churches and sects. In Scripture, however, and the early Christian writers, it has an application sufficiently distinct from partial interpretations. Antichrist, according to St John, is the ruling spirit of error, the enemy of the truth of the Gospel as it is displayed in the divinity and holiness of Christ. This is the primary meaning of the term, and we are led at once to consider it as the proper title of Satan. But the same apostle speaks of the existence of many antichrists; whence we learn that it is applicable to any being who opposes Christ in the high places of spiritual wickedness. St Paul speaks of "the man of sin" as not yet revealed, and it is supposed by most interpreters that *antichrist* is to be understood as the object alluded to by the apostle; but if we attend strictly to his words, the antichrist of whom he spoke must have been then, and at the time when he was writing, "opposing and exalting himself above all that is called God," although awaiting some distant season for the open display of his power and wickedness. Justin Martyr, in his *Dialogue with Tryphon*, describes him as exercising his wrath against Christians with especial fury in the period immediately preceding the Second Advent. Cyril of Jerusalem represents him as reigning three years and six months preparatory to the entire destruction of his dominion at the second coming of Christ. The same Father says that he will deceive both Jews and Gentiles; the former, by re-

presenting himself as the Messiah; the latter, by his magical arts and incantations. St Chrysostom observes, on the passage in the 2d Epistle to the Thessalonians, that antichrist will not lead men to idolatry, but will rather abolish the worship of false gods as well as that of the true God, commanding the world to worship himself alone as the only Deity.

These views of the early writers, as well as the expressions of Scripture, have been perverted by many men of warm imaginations to the worst purposes of controversy. The effects of general corruption have often been charged upon offices and individuals; and the appellation of *antichrist* as readily applied to them as if it had actually been coupled in Scripture with their name and titles.

ANTICHTHONES (ἀντί and χθών), in *Geography*, an appellation given to the inhabitants of opposite hemispheres.

ANTICIPATION, in *Music*. See MUSIC.

ANTICLIMAX, in *Rhetoric*, a declension in the force or dignity of the ideas at the close of a sentence, as in the following celebrated distich:—

> "The great Dalhousie, he, the god of war,
> *Lieutenant-colonel to the earl of Mar.*"

ANTICOSTI, a barren island in the Gulf of St Lawrence, North America, with an estimated area of 2600 square miles. There are no good harbours on its coast, and the southern shore is low and dangerous. The lighthouse on its south-west point is in Lat. 49. 23. 53. N. Long. 63. 38. 47. W.

ANTICUM, in *Ancient Architecture*, the front door of a house, called also *janua*, and in Greek by the several terms θυρὰ αὔλειος, αὔλεια, αὔλια. The back door in Roman houses was called *posticum*, *postica*, or *posticula*, in Greek παράθυρα or παραθύριον; and Cicero (*Post Red.* 6) uses *pseudothyron* in contradistinction to *janua*. It was accounted ominous to set the left foot on the threshold; hence the steps of a temple were of an uneven number, so that by commencing the ascent with the right foot, the danger would be avoided. (See Vitruvius, iii. 4.) The door of a temple was called *foris* and *valva*, in Greek σανίς, κλισίας, or θύρετρον, these words being generally used in their plural form to denote the two halves of a folding-door. Bivalve doors were also used in private apartments.

ANTICYRA, in *Ancient Geography*, the name of three cities of Greece. (1.) In Phocis, on the Bay of Anticyra, in the Corinthian Gulf. Its modern name is Aspra Spitia, where some remains are still visible. (2.) In Thessaly, on the right bank of the River Sperchius, near its mouth. Both these places were celebrated for their hellebore. (3.) In Locris, on the left side of the entrance to the Corinthian Gulf, and not far from Naupactus.

ANTIDESMA, a genus of plants of the class Diœcia, and order Pentandria.

ANTIDORON, in *Ecclesiastical Writers*, a name given by the Greeks to the consecrated bread, out of which the middle part, marked by the cross, wherein the consecration resides, being taken away by the priest, the remainder is distributed after mass to the poor.

ANTIDOSIS, in *Antiquity*, denotes an exchange of estates, practised by the Greeks on certain occasions with peculiar ceremonies, and first instituted by Solon.

When a person was nominated to an office, the expense of which he was not able to support, he had recourse to the antidosis; that is, he was to seek some other citizen of better substance than himself, who was free from this and other offices; in which case the former was excused. In case the person thus substituted denied himself to be the richer, they were to exchange estates after this manner: the doors of their houses were shut up and sealed, that nothing might be conveyed away; both took an oath to make a faithful discovery of all their effects, except what lay in the silver mines, which by the laws were exempted from all imposts. Accordingly, within three days, a full discovery and exchange of estates was made.

ANTIGALACTIC, a term applied to medicines and other means employed to diminish the secretion of milk.

ANTIGONUS I., one of the captains of Alexander the Great, was the son of Philip a Macedonian nobleman. After Alexander's death, in B.C. 323, a division of the provinces taking place, Pamphylia, Lycia, and Phrygia Major fell to his share. But Perdiccas, well acquainted with his ambitious spirit and great abilities, determined to divest him of his government, and laid plans for his life, by bringing various accusations against him. Antigonus, aware of the danger, retired with his son Demetrius into Greece, where he obtained the favour and protection of Antipater, B.C. 321; and when soon after, on the death of Perdiccas, a new division took place, he was invested not only with the government of the former provinces, but also with that of Susiana. He was likewise intrusted with the command of the Macedonian household troops; and upon Eumenes being declared a public enemy, he received orders to prosecute the war against him with the utmost vigour. At the commencement of this war, Eumenes suffered a total overthrow, and was obliged to retire with only 600 brave followers to a castle situated on an inaccessible rock, where he might rest in safety from all the assaults of Antigonus. In the interval, his friends assembled a new army for his relief, which was routed by Antigonus, who now began to exhibit the great projects of his ambition. Polysperchon succeeding to the tutorship of the young king of Macedon after Antipater's death, Antigonus resolved to set himself up as lord of all Asia. On account of the great power of Eumenes, he greatly desired to gain him over to his interest; but that faithful commander, effecting his escape from the fortress where he was closely blockaded, raised an army, and was appointed the royal general in Asia. The governors in Upper Asia co-operating with him, he succeeded in several engagements against Antigonus; but was at last delivered up to him through treachery, and put to death. Upon this the governor of Upper Asia yielded to Antigonus. Those whom he suspected, he either sacrificed to his resentment or displaced from their offices. Then seizing upon all the treasures at Susa, he directed his march towards Babylon, of which city Seleucus was governor. Seleucus fled to Ptolemy, and entered into a league with him, together with Lysimachus and Cassander, with the intention of giving a check to the exorbitant power of Antigonus, who, notwithstanding this, made a successful attempt upon the provinces of Syria and Phœnicia. But these provinces were soon after recovered by Ptolemy, who defeated his son Demetrius, while he himself was employed in repelling Cassander, who had made rapid progress in Lesser Asia. They were again taken by Antigonus, who, flushed with success, planned an expedition against the Nabathæan Arabs dwelling in the deserts adjacent to Judæa; but on the first enterprise against the town of Petra, his general Athenæus, with almost all his troops, were cut to pieces by the Arabs. Antigonus then sent his son against them, who returned after forcing them to reasonable terms. Demetrius then expelled Seleucus from Babylon; and success attending his arms wherever he went, the confederates were obliged to make a treaty with Antigonus, in which it was stipulated that he should remain in possession of all Asia, but that the Greek cities should continue in possession of their liberty. This agreement was soon violated, under the pretence that garrisons had been placed in some of these cities by Antigonus. At first Ptolemy made a successful descent into Lesser Asia, and on several of the islands of the Archipelago; but he was at length defeated in a sea-fight by the successful arms of Demetrius, who also took the island of Cyprus, with many prisoners.

On this victory Antigonus was so elated that he assumed the title of king, and bestowed the same upon his son; and from that time, B.C. 306, his reign in Asia, and that of Ptolemy in Egypt, and of the other captains of Alexander in their respective governments, properly commence.

Irritated at the hostile conduct of Ptolemy, Antigonus prepared a numerous army and a formidable fleet; and having taken the command of the army, he gave that of the fleet to Demetrius, and hastened to attack Ptolemy in his own dominions. After enduring the severest hardships, they met in the vicinity of Mount Casius; but Ptolemy acted with such valour and address that Antigonus could gain no advantage over him; and after several fruitless attempts, he abandoned the undertaking. Demetrius attempted the reduction of Rhodes; but meeting with obstinate resistance, he was obliged to make a treaty upon the best terms that he could, having been called to join Antigonus against Cassander, who at this time had formed a confederacy with Seleucus and Lysimachus. When Demetrius united his forces with those of Antigonus, they advanced to Phrygia, and having met the enemy at Ipsus, a decisive battle was fought, in which Antigonus fell in the 81st year of his age, B.C. 301.

ANTIGONUS II., *Gonatas*, son of Demetrius Poliorcetes, was the grandson of the former Antigonus. His character was eminently distinguished by humanity and mildness of disposition. When he besieged Thebes under the command of his father, he strongly remonstrated against the loss of so many lives for such an insignificant object. Filial affection was so powerful in his mind, that when his father was taken prisoner by Seleucus, he generously offered himself in his stead; and being rejected, he wore deep mourning, and refrained from all festivals and amusements during his father's imprisonment. By the death of his father, in B.C. 283, he became master of all the European dominions of Demetrius, together with the kingdom of Macedon, and various other cities in Greece. The Gauls invading his country, he defeated and expelled them; but was soon after routed by Pyrrhus, king of Epirus. Some time after, however, Pyrrhus was slain at Argos; and when his head was brought to Antigonus by his son, he expressed the highest displeasure, and throwing his robe over it, gave orders to search for the body, and to inter it with all funeral honours.

In the evening of his reign he so cultivated the arts of peace, that he secured the affections of his subjects both to himself and his descendants. The taking of the citadel of Corinth by intrigue was the meanest action of his reign; but he improved that event in maintaining the freedom of the smaller states of Greece, and in increasing his own dominions. The Achæans, and Aratus their famous chief, vigorously opposed his measures, and at length recovered Corinth; but Antigonus was so inclined to peace, that notwithstanding this event, he pursued his wonted plan, and left his kingdom in peace, about the 80th year of his life and the 44th of his reign, B.C. 239.

ANTIGRAPHUS, a name used by writers in the middle ages for a secretary or chancellor. The antigraphus is sometimes called *archigraphus*. The term is also applied by ecclesiastical writers to an abbreviator of the papal letters; in which sense the word is used by Pope Gregory the Great in his register.

ANTIGUA, one of the Antilles or Caribbee Islands, situated 20 leagues east of St Christophers, in Long. 61. 45. W. and Lat. 17. 6. N. It is about 50 miles in circumference, and is reckoned the largest of the British Leeward Islands. This island having no rivers, and but few springs, or such as are brackish, the inhabitants are obliged to preserve the rain-water in cisterns. The air here is not so wholesome as in the neighbouring islands, and it is more subject to hurricanes; but it has excellent harbours, particularly English Harbour, which is capable of receiving the largest man-of-war in the navy. The principal trade, however, is carried on in the harbour of St John's the capital, situated in the north-west part of the island, and which has water sufficiently deep for merchant vessels. The island contains an area of 108 British square miles, equal to 69,120 acres, of which about 34,000 are appropriated to the growth of sugar, including pasture grounds. The other staples are cotton, ginger, and tobacco.

The first attempt to establish a settlement in Antigua was made by Sir Thomas Warner, but it did not succeed. It was afterwards granted by Charles II. to Lord Willoughby, who in 1632 settled a colony upon it. In 1850 the population was 37,357, of whom only about 2000 were whites. The estimated value of the imports in 1851 was L.198,425 sterling; of the exports, L.219,239, being an increase over the preceding year of L.34,802, and L.87,357 respectively. In 1851 the ordinary revenue was L.21,888, and the expenditure L.21,193. The island is under a governor, council, and assembly.

ANTILEGOMENA (ἀντιλεγόμενα, *contradicted* or *disputed*), an epithet applied by the early Christian writers to denote those books of the New Testament which, although sometimes publicly read in the churches, were not for a considerable time admitted to be genuine, or received into the canon of Scripture. These books are so denominated in contradistinction to the *Homologoumena*, or universally acknowledged writings. The following is a catalogue of the *Antilegomena*:—*The Second Epistle of St Peter; the Epistle of St James; the Epistle of St Jude; the Second and Third Epistles of St John; the Apocalypse*, or *Revelation of St John; the Epistle to the Hebrews.*

The earliest notice which we have of this distinction is that contained in the *Ecclesiastical History* of Eusebius, who flourished A.D. 270–340.

ANTILLES, the French name for the Caribbee Islands.

ANTILOGARITHM, the complement of the logarithm of a sine, tangent, or secant; or the difference of that logarithm from the logarithm of 90 degrees.

ANTILOGY, in *Literature*, an inconsistency between two or more passages of the same book.

ANTILOIMICS (ἀντί and λοιμός, *pestilence*), remedies against infection, of which the most efficacious is chlorine, the next in power the vapour of nitric acid, and thirdly, that of the muriatic acid.

ANTIMENSIUM, a kind of consecrated table-cloth, occasionally used in places where there is no proper altar.

ANTIMENSIUM, in the Greek church, answers to the *altare portabile*, or portable altar, in the Latin church. They are both only of late invention, though Habertus would have them as old as St Basil. But Durant and Bona do not pretend to find them in any author before the time of Bede and Charlemagne.—*Antimensia* is also applied to other tables used in offices of religion, besides those whereon the eucharist is administered; such, *e. g.*, are those whereon the host is exposed, &c.
